The use of chiral additives with a rhodium complex also leads to cyclopropanes enantioselectively.[2301] An important chiral rhodium species is Rh_2(*S*-DOSP)$_4$,[2302] which leads to cyclopropanes with excellent enantioselectivity in carbene cyclopropanation reactions.[2303] Asymmetric, intramolecular cyclopropanation reactions have been reported.[2304] The copper catalyzed diazoester cyclopropanation was reported in an ionic liquid.[2305] It is noted that the reaction of a diazoester with a chiral dirhodium catalyst leads to β-lactones with modest enantioselectivity.[2306] Phosphonate esters have been incorporated into the diazo compound.[2307]

Triple-bond compounds[2308] react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they rearrange to allenes.[2309] Cyclopropenones (p. 73) are obtained by hydrolysis of dihalocyclopropenes.[2310]

Most carbenes are electrophilic, and, in accord with this, electron-donating substituents on the alkene increase the rate of the reaction, and electron-withdrawing groups decrease it,[2311] although the range of relative rates is not very great.[2312] As discussed on p. 284, carbenes in the singlet state (which is the most common state) react stereospecifically and syn,[2313] probably by a one-step mechanism,[2314] similar

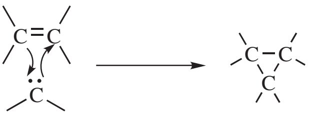
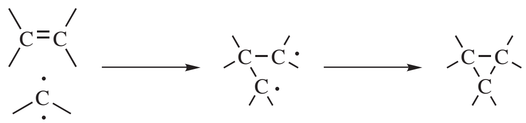
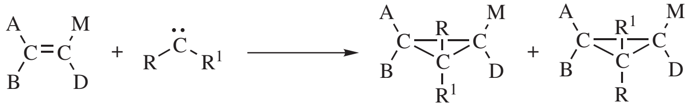
to mechanism *a* of **15-60** and **15-63**:



Infrared spectra of a carbene and the cyclopropane product have been observed in an argon matrix at 12–45 K.[2315] Carbenes in the triplet state react nonstereospecifically,[2316] probably by a diradical mechanism, similar to mechanism *b* of **15-49** and **15-63**:

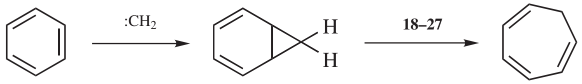


For carbenes or carbenoids of the type R—C—R′ there is another aspect of stereochemistry.[2317] When these species are added to all but symmetrical alkenes, two isomers are possible, even if the four groups originally on the double–bond carbons maintain their configurations:



Which isomer is predominantly formed depends on R, R′, and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species (R′ = H), and in these studies it is found that aryl groups generally prefer the more substituted side (syn addition) while carbethoxy groups usually show anti stereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for syn addition. Beyond this, it is difficult to make simple generalizations.

Carbenes are so reactive that they add to the "double bonds" of aromatic rings.[2318] The products are usually unstable and rearrange to give ring expansion. Carbene reacts with benzene to give cycloheptatriene (**216**),[2319]



Norcaradiene **216**

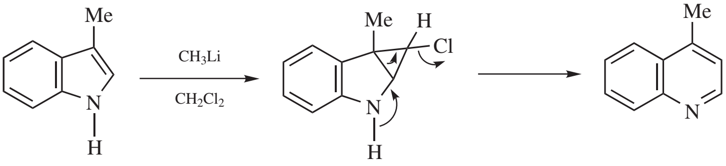
but not all carbenes are reactive enough to add to benzene. The norcaradiene intermediate cannot be isolated in this case[2320] (it undergoes an electrocyclic rearrangement, **18-27**), although certain substituted norcaradienes, for example, the product of addition of: $C(CN)_2$ to benzene,[2321] have been isolated.[2322] With: CH_2, insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding: CH_2 to benzene rings without the use of free carbene is the catalytic decomposition of diazomethane (CH_2N_2) in the aromatic compound as solvent with CuCl or CuBr.[2323] By this method better yields of cycloheptatrienes are obtained without insertion side products. Picosecond optical grating calorimetry has been used to investigate the photochemical decomposition of diazomethane in benzene, and it appears that a transient is formed that is consistent with a weak complex between singlet methylene and benzene.[2324] Chlorocarbene, :CHCl, is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density. Pyrroles and indoles can be expanded, respectively, to pyridines and quinolines by treatment with halocarbenes[2325] via the initially formed adduct **217** in the case of the indole.



217

In such cases, a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring expansion can occur even with non–aromatic compounds, when the driving force is supplied by relief of strain (see **218**).[2326]

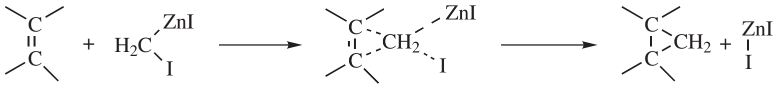
As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons–Smith procedure* accomplishes the same result without a free carbene intermediate and without insertion side products.[2327] This procedure involves treatment of the double-bond compound with CH_2I_2 and a Zn–Cu couple and leads to cyclopropane derivatives in good yields.[2328] The Zn–Cu couple can be prepared in several ways,[2329] of which heating Zn dust with CuCl in ether under nitrogen[2330] is particularly convenient. The reaction has also been done with unactivated zinc and ultrasound.[2331] When $TiCl_4$ is used along with Zn and CuCl, CH_2I_2 can be replaced by the cheaper CH_2Br_2.[2332] The actual attacking species is an organozinc intermediate, probably $(ICH_2)_2Zn{\bullet}ZnI_2$, which is stable enough for isolable solutions.[2333] An X-ray crystallographic investigation of the intermediate, complexed with a diether, has been reported.[2334] The addition is stereospecifically syn, and a concerted mechanism[2335] is likely, perhaps[2336]



Asymmetric induction is possible when chiral additives are used.[2337] With the Simmons–Smith procedure, as with free carbenes, conjugated dienes give 1,2-addition,[2338] and allenes give methylenecyclopropanes or spiropentanes.[2339]

An alternative way of carrying out the Simmons–Smith reaction is by treatment of the substrate with CH_2I_2 or another dihalomethane and Et_2Zn in ether.[2340] This method can be adapted to the introduction of RCH and ArCH by the use of $RCHI_2$

or $ArCHI_2$ instead of the dihalomethane.[2341] The reaction is compatible with other functionality in the carbenoid complex. The reaction of RCO_2CH_2I with diethyl zinc and an alkene under photolysis conditions give a cyclopropane.[2342] Chiral additives lead to enantioselectivity in the cyclopropanation reaction.[2343] In another method, CH_2I_2 or $MeCHI_2$ is used along with an alane R_3Al to transfer CH_2 or CHMe.[2344] Titanium complexes have been used similarly.[2345] Samarium and CH_2I_2 has been used for the cyclopropanation of conjugated amides.[2346] For the conversion of enolates to cyclopropanols, CH_2I_2 has been used along with SmI_2.[2347]

Other cyclopropanation techniques have been developed. Treatment of an alkene with $ArCH(SnBu_3)OCO_2Me$ and $BF_3{\bullet}OEt_2$ leads to the cyclopropane with high cis-selectivity.[2348] Diodomethane in the presence of isopropylmagnesium chloride has been used to cyclopropanate allyl alcohols.[2349]

The Simmons–Smith reaction is the basis of a method for the indirect α methylation of a ketone.[2350] The ketone (illustrated for cyclohexanone) is first converted to an enol ether, an enamine (**16-13**) or silyl enol ether[2351] (**12-17**) and cyclopropanation via the Simmons–Smith reaction is followed by hydrolysis to give the α methylated ketone. A related procedure using diethylzinc and diiodomethane allows ketones to be chain-extended by one carbon.[2352] In another variation, phenols can be ortho-methylated in one laboratory step, by treatment with Et_2Zn and CH_2I_2.[2353]

Diazoesters react with amines with a rhodium catalyst to give α-amino esters.[2354] Diazoesters also react with aldehydes and a rhodium catalyst, and the product is an α,β-epoxy ester.[2355] Diazoalkanes react similarly with aldehydes to give an alkene ($Me_3SiCH{=}N_2 + ArCHO \rightarrow ArCH{=}CHOSiMe_3$).[2356]

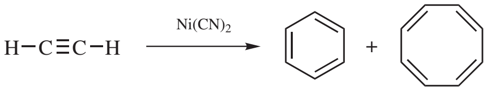
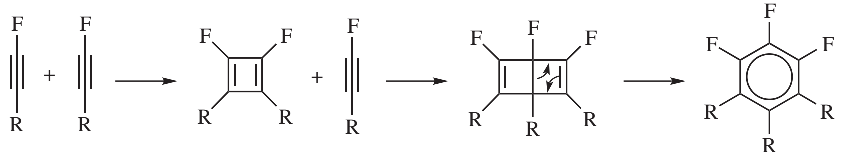
15-65 Trimerization and Tetramerization of Alkynes



Aromatic compounds can be prepared by cyclotrimerization of alkynes[2357] or triynes. Cyclotrimerization is possible by heating to 450–600°C with no catalyst.[2358] The *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF gave 1,2,3-tri-*tert*-butyl-4,5,6-trifluorobenzene (**220**), the first time three adjacent *tert*-butyl groups had been put onto a benzene ring.[2359] The fact that this is a head-to-head joining allows formation of **220** from two alkynes. The fact that **219** (a Dewar benzene) was also isolated lends support to this scheme.[2360] Three equivalents of 3-hexyne trimerized to hexaethylbenzene at 200°C in the presence of Si_2Cl_6.[2361]



R = *tert*-butyl **219** **220**

When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.[2362] It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes.[2363] This reaction has been used to prepare very crowded

molecules. Diisopropylacetylene was trimerized over $CO_2(CO)_8$[2364] and over $Hg[Co(CO)_4]_2$ to hexaisopropylbenzene.[2365] The six isopropyl groups are not free to rotate but are lined up perpendicular to the plane of the benzene ring. Highly substituted benzene derivatives have also been prepared using a rhodium,[2366] nickel,[2367] titanium,[2368] molybdenum,[2369] ruthenium,[2370] cobalt,[2371] or a palladium[2372] catalyst. Alkynes react with allenes and a nickel catalyst go give highly substituted benzene derivatives.[2373] Conjugated ketones react with internal alkynes with Me_3Al and a nickel catalyst[2374] leads to an aromatic ring fused to a cyclic ketone after reaction with DBU and air.[2375] *N*-Aryl chloroimines react with alkynes and a rhodium catalyst to give quinolines,[2376] as do *N*-aryl alkynyl imines with a tungsten complex.[2377]

An intramolecular cyclotrimerization has been reported by condensation of a diyne[2378] with an alkyne in the presence of a palladium,[2379] molybdenum,[2380] nickel,[2381] rhodium,[2382] iridium,[2383] or ruthenium catalyst.[2384] Triynes have been

similarly condensed with a rhodium catalyst.[2385] The internal cyclotrimerization of a triyne, utilizing a siloxy tether and a cobalt catalyst has been reported.[2386] Fused ring aromatic compounds are prepared by this method. Similar results were obtained from diynes and allenes with a nickel catalyst.[2387] bis(Enynes) are cyclized to bicyclic arenes using a palladium catalyst.[2388] Diynes with nitriles and a ruthenium catalyst lead to isoquinolines.[2389] Pyridines fused to carboxylic rings can be prepared by similar methodology using a cyanoamine and a cobalt catalyst.[2390] In the presence of $PhMe_2SiH$, CO and a rhodium catalyst, a nonconjugated triyne leads to a tricyclic compound in which a benzene ring is fused to two carbocyclic rings.[2391] Internal cyclotrimerization of an aryl alkynyl ketone where the aryl group has an *ortho* trimethylsiylalkyne substituent gives a tetracyclic naphthalene derivative with a fused cyclopentanone unit.[2392] An isocyanate (Ar—N=C=O) reacts with a diyne and a ruthenium catalyst to give a bicyclic pyridone.[2393] Benzene derivatives with ortho alkyne units can be converted to naphthalene derivatives in aqueous NaOH with hydrazine, Te, $NaBH_4$ and sonication.[2394] Benzene derivatives having ortho imine and alkyne substituents give an isoquinoline when treated with iodine[2395] or with a palladium catalyst.[2396] Imino and iodo substituents with a silyl alkyne and a palladium catalyst leads to an isoquinoline.[2397] Vinyl and alkyne substituents with a ruthenium catalyst lead to naphthalene derivatives.[2398] Ortho alkynyl and epoxy substituents leads to β-naphthols using a ruthenium catalyst.[2399] Cyclotrimerization occurs with alkynyl boronic esters.[2400]

In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene RC≡CH. The chief product is usually the 1,2,4-isomer,[2401] with lesser amounts of the 1,3,15-isomer also generally obtained, but little if any of the 1,2,3-isomer. The mechanism of

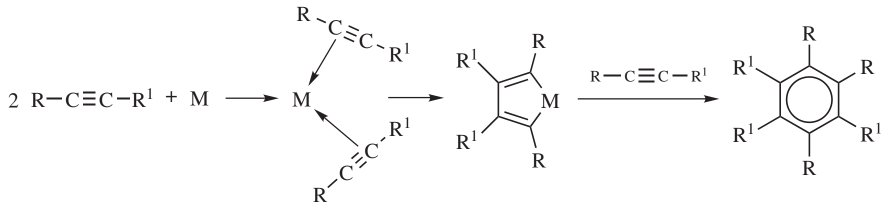
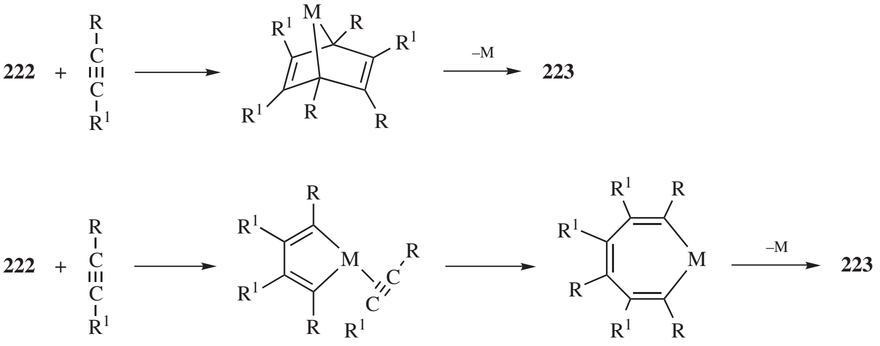
the catalyzed



reaction to form benzenes[2402] is believed to go through a species **221** in which two molecules of alkyne coordinate with the metal, and another species **222**, a five-membered heterocyclic intermediate.[2403] Such intermediates (where M = Rh, Ir, Zr,[2404] or Ni) have been isolated and shown to give benzenes (**223**) when treated with alkynes.[2405] Note that this pathway accounts for the predominant formation of the 1,2,4-isomer. Two possibilities for the last step are a Diels–Alder reaction, and a ring expansion, each followed by extrusion of the metal:[2406]



[2402]For studies of the mechanism of the reaction that produces cyclooctatetraenes, see Diercks, R.; Stamp, L.; Kopf, J.; Tom Dieck, H. *Angew. Chem. Int. Ed.* ***1984***, *23*, 893; Colborn, R.E.; Vollhardt, K.P.C. *J. Am. Chem. Soc.* ***1986***, *108*, 5470; Lawrie, C.J.; Gable, K.P.; Carpenter, B.K. *Organometallics* ***1989***, *8*, 2274.

Chem. Soc.* ***1977***, *99*, 1666.

[2406]There is evidence that the mechanism of the last step more likely resembles the Diels–Alder pathway than the ring expansion pathway: Bianchini, C.; Caulton, K.G.; Chardon, C.; Eisenstein, O.; Folting, K.; Johnson, T.J.; Meli, A.; Peruzzini, M.; Raucher, D.J.; Streib, W.E.; Vizza, F. *J. Am. Chem. Soc.* ***1991***, *113*, 5127.

In at least one case the mechanism is different, going through a cyclobutadiene–nickel complex (see p. 76), which has been isolated.[2407] Similar results were obtained with a titanium complex.[2408] Using a mixture of $PdCl_2$ and $CuCl_2$, however, aliphatic alkynes are converted to the 1,3,5-trialkyl benzene derivative.[2409]

Alkoxy chromium carbenes (Fischer carbene complexes) react with phenylalkynes to give naphthalene derivatives.[2410] These chromium carbenes react with alkynyl boronates, cerium(IV) compounds, and then PhBr and a palladium catalyst to give a naphthoquinone.[2411] Diynes react to give cyclotrimerization.[2412] It is noted that vinyl chromium carbenes react directly with alkynes to give spirocyclic compounds (spiro[4.4]nona-1,3,6-trienes).[2413] Benzofurans can be prepared using methoxy carbenes.[2414] Amino-substituted chromium carbenes react with alkynes and then silica to give substituted benzene derivatives that have an aminoalkyl ($-NR_2$) substituent.[2415] Imino-substituted chromium carbenes react with alkynes to give pyrrole derivatives.[2416] Fischer carbene complexes react with alkynes to give the *Dötz benzannulation*,[2417] giving *p*-alkoxylphenol derivatives. Modification of this basic technique can lead to eight-membered ring carbocycles (see **15-66**).[2418]

When benzene, in the gas phase, was adsorbed onto a surface of 10% rhodium-on-alumina, the reverse reaction took place, and acetylene was formed.[2419]

In a related reaction, heating ketones in the presence of $TlCl_3OTf$ leads to 1,3,5-trisubstituted arenes.[2420] Heating acetophenone with $TiCl_4$ gives 1,3,5-triphenylbenzene.[2421] Nitriles react with 2 mol of acetylene, in the presence of a cobalt catalyst, to give 2-substituted pyridines.[2422] Propargyl amines react with cyclohexanone derivatives and a gold complex give tetrahydroquinolines.[2423] Treatment of alkynes with Cp_2ZrEt_2 followed by reaction with acetonitrile and then a second alkyne with a nickel catalyst gives a highly substituted pyridine.[2424] This reaction can be done intramolecularly using a photochemically induced reaction with a

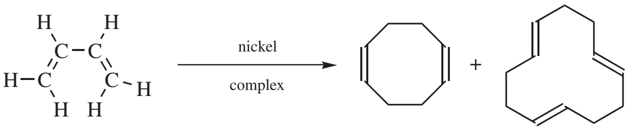
cobalt catalyst and *p*-TolCN to give pyridines incorporated into macrocycles.[2425] Alkynyl esters react with enamino esters with a $ZnBr_2$ catalyst to give substituted pyridines.[2426] α-Halo oxime ethers react with alkynes and Grignard reagents, with a mixture of palladium and copper catalysts, to give pyrimidines.[2427] Triketones fix nitrogen gas in the presence of $TiCl_4$ and lithium metal to form bicyclic pyrrole derivatives.[2428]

OS **VII**, 256; **IX**, 1; **80**, 93.

15-66 Other Cycloaddition Reactions

***cyclo*-[But-2-en-1,4-diyl]-1/4/addition**, and so on



Cycloaddition reactions other than [4 + 2], [3 + 2], or [2 + 2] are possible, often providing synthetically useful routes to cyclic compounds. Conjugated dienes can be dimerized or trimerized at their 1,4 positions (formally, [4 + 4] and [4 + 4 + 4]-cycloadditions) by treatment with certain complexes or other transition-metal compounds.[2429] Thus butadiene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.[2430] The relative amount of each product can be controlled by use of the proper catalyst. For example, $Ni{:}P(OC_6H_4\text{—}o\text{—}Ph)_3$ gives predominant dimerization, while Ni(cyclooctadiene)$_2$ gives mostly trimerization. The products arise, not by direct 1,4 to 1,4 attack, but by stepwise mechanisms involving metal–alkene complexes.[2431] The rhodium catalyzed intramolecular cycloaddition of a furan with a conjugated diazoester gives a [3 + 4]-cycloadduct.[2432] The suprafacial thermal addition of an allylic cation to a diene (a [4 + 3]-cycloaddition) is allowed by the Woodward–Hoffmann rules (this reaction would

Res.* ***1979***, *12*, 61.

be expected to follow the same rules as the Diels–Alder reaction[2433]). Chiral cations have been used in [4 + 3]-cycloadditions.[2434]

As we saw in **15-60**, the Woodward–Hoffmann rules allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is 4*n*+2 and photochemically if the number is 4*n*. Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight-membered or greater, concerted mechanisms, although allowed by orbital symmetry for the cases stated, become difficult to achieve because of the entropy factor (the two ends of one system must simultaneously encounter the two ends of the other), unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight-membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct [4 + 4]- or [4 + 4 + 4]-cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes. Some examples are

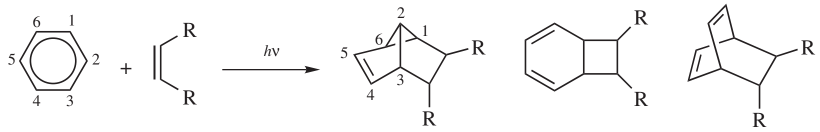
Ref. [2438]

Benzene rings can undergo photochemical cycloaddition with alkenes.[2439] The major product is usually the 1,3-addition product **224** (in which a three-membered ring has also been formed), although some of the 1,2 product **225**



224 **225** **226**

(**15-63**) is sometimes formed as well. (**225** is usually the main product where the alkene bears electron-withdrawing groups and the aromatic compound electron-donating groups, or vice versa.) The 1,4 product **226** is rarely formed. The reaction has also been run with benzenes substituted with alkyl, halo, OR, CN, and other groups, and with acyclic and cyclic alkenes bearing various groups.[2440]

A [2 + 2 + 2]-cycloaddition reaction is also known, facilitated by $Ni(cod)_2$[2441] or a cobalt catalyst.[2442] [2 + 2 + 1]-Cycloaddition is known.[2443] A cobalt catalyst is used for a [4 + 2 + 2]-cycloaddition of 1,3-butadiene and bicyclo[2.2.2]octa-2,5-diene.[2444] Eight-membered rings are products by a rhodium catalyzed [4 + 2 + 2]-cycloaddition.[2445] Chromium catalysts are available for [6 + 4]-cycloadditions.[2446]

CHAPTER 16

Addition to Carbon–Hetero Multiple Bonds

MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon–oxygen, carbon–nitrogen, and carbon–sulfur double bonds, and the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon–carbon multiple bonds considered in Chapter 15.[1] Most of the questions that concerned us there either do not arise here or can be answered very simply. Since C=O, C=N, and C≡N bonds are strongly polar, with the carbon always the positive end (except for isocyanides, see p. 1466), there is never any doubt about the *orientation* of unsymmetrical addition to these bonds. Nucleophilic attacking species always go to the carbon and electrophilic species to the oxygen or nitrogen. Additions to C=S bonds are much less common,[2] but in these cases the addition can be in the other direction.[3] For example, thiobenzophenone ($Ph_2C{=}S$), when treated with phenyllithium gives, after hydrolysis, benzhydryl phenyl sulfide (Ph_2CHSPh).[4]

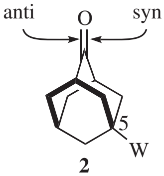
In addition of YH to a ketone to give **1** the product has a stereogenic carbon, but unless there is chirality in R or R′ or YH is optically active, the product must be a racemic mixture because there is no facial bias about the carbonyl. The same holds true for C=N and C=S bonds, since in none of these cases can chirality be present at the heteroatom. The stereochemistry of addition of a single YH to the carbon–nitrogen triple bond could be investigated, since the product can exist in (*E*) and (*Z*) forms (p. 183), but these reactions generally give imine products that undergo further reaction. Of course, if R or R′ *is* chiral, a racemic mixture will not always arise and the stereochemistry of addition can be studied in such cases. Cram's rule (p. 168) allows us to predict the direction of attack of Y in many cases.[5] However, even in this type of study, the relative directions of attack of Y and H are not determined, but only the direction of attack of Y with respect to the rest of the substrate molecule.



2

On p. 1023, it was mentioned that electronic effects can play a part in determining which face of a carbon–carbon double bond is attacked. The same applies to additions to carbonyl groups. For example, in 5-substituted adamantanones (**2**) electron-withdrawing (*-I*) groups W cause the attack to come from the syn face, while electron-donating groups cause it to come from the anti face.[6] In 5,6-disubstituted norborn-2-en-7-one systems, the carbonyl appears to tilt away from the π-bond, with reduction occurring from the more hindered face.[7] An *ab initio* study of nucleophilic addition to 4-*tert*-butylcyclohexanones attempted to predict π-facial selectivity in that system.[8]

The mechanistic picture is further simplified by the fact that free-radical additions to carbon–heteroatom double bonds are not as prevalent.[9] In most cases, it

[5]For a discussion of such rules, see Eliel, E.L. *The Stereochemistry of Carbon Compounds*, McGraw-Hill, NY, ***1962***, pp. 68–74. is the nucleophile that forms the first new bond to carbon, and these reactions are regarded as *nucleophilic additions*, which can be represented thus (for the C=O bond, analogously for the others):

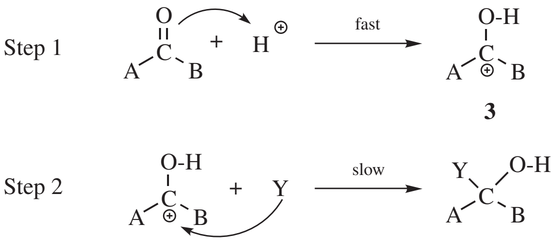
The electrophile shown in step 2 is the proton. In almost all the reactions considered in this chapter, the electrophilic atom is either hydrogen or carbon. Note that step 1 is exactly the same as step 1 of the tetrahedral mechanism of nucleophilic substitution at a carbonyl carbon (p. 1255), but carbon groups (A, B = H, alkyl aryl, etc.) are poor leaving groups so that substitution does not compete with addition. For carboxylic acids and their derivatives (B = OH, OR, NH_2, etc.) much better leaving groups are available and acyl substitution predominates (p. 1254). It is thus the nature of A and B that determines whether a nucleophilic attack at a carbon–heteroatom multiple bond will lead to substitution or addition.

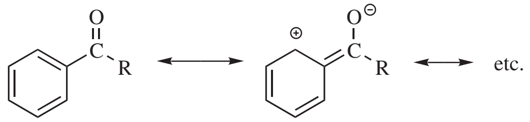
It is also possible for the heteroatom (oxygen in a carbonyl) to react as a base, attacking the electrophilic species. This species is most often a proton and the mechanism is



Whether the nucleophile attacks the carbon or the heteroatom attacks the electrophilic species, the rate-determining step is usually the one involving nucleophilic attack. It may be observed that many of these reactions can be catalyzed by both acids and bases.[10] Bases catalyze the reaction by converting a reagent of the form YH to the more powerful nucleophile Y^- (see p. 490). Acids catalyze it by converting the substrate to an heteroatom-stabilized cation (formation of **3**), thus making it more attractive to nucleophilic attack. Similar catalysis can also be found with metallic ions (e.g., Ag^+) which act here as Lewis acids.[11] We have mentioned before (p. 242) that ions of type **3** are comparatively stable carbocations because the positive charge is spread by resonance.

[10]For a discussion of acid and base catalysis in these reactions, see Jencks, W.P.; Gilbert, H.F. *Pure Appl. Chem.* ***1977***, *49*, 1021.
[11]Toromanoff, E. *Bull. Soc. Chim. Fr.* ***1962***, 1190.

Reactivity factors in additions to carbon–heteroatom multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution.[12] If A and/or B are electron-donating groups, rates are decreased. Electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule, but is lost on going to the intermediate:



Double bonds in conjugation with the carbon–heteroatom multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4-addition (p. 1008). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones like hexamethylacetone and dineopentyl ketone either do not undergo many of these reactions or require extreme conditions.

Nucleophilic Substitution at an Aliphatic Trigonal Carbon: The Tetrahedral Mechanism

All the mechanisms so far discussed take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double bonded to an oxygen, a sulfur, or a nitrogen. Substitution at a carbonyl group (or the corresponding nitrogen and sulfur analogs) most often proceeds by a second-order mechanism, which in this book is called the *tetrahedral*[13] *mechanism.*[14] The IUPAC designation is $A_N + D_N$. The S_N1 mechanisms, involving carbocations, are sometimes found with these substrates, especially with essentially ionic substrates such as RCO^+ BF_4^-; there is evidence that in certain cases simple S_N2 mechanisms can take place, especially with a very good leaving group such as Cl^-;[15]

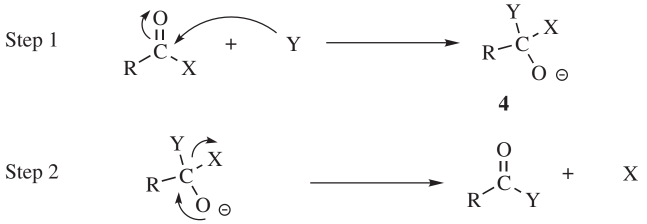
[12]For a review of the reactivity of nitriles, see Schaefer, F.C., in Rappoport, Z. *The Chemistry of the Cyano Group*, Wiley, NY, ***1970***, pp. 239–305.

[13]This mechanism has also been called the "additionelimination mechanism," but in this book we limit this term to the type of mechanism shown on p. $$$.

[14]For reviews of this mechanism, see Talbot, R.J.E., in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 10, Elsevier, NY, ***1972***, pp. 209–223; Jencks, W.P. *Catalysis in Chemistry and Enzymology*, McGraw-Hill, NY, ***1969***, pp. 463–554; Satchell, D.P.N.; Satchell, R.S., in Patai, S. *The Chemistry of Carboxylic Acids and Esters*, Wiley, NY, ***1969***, pp. 375–452; Johnson, S.L. *Adv. Phys. Org. Chem.* ***1967***, *5*, 237.

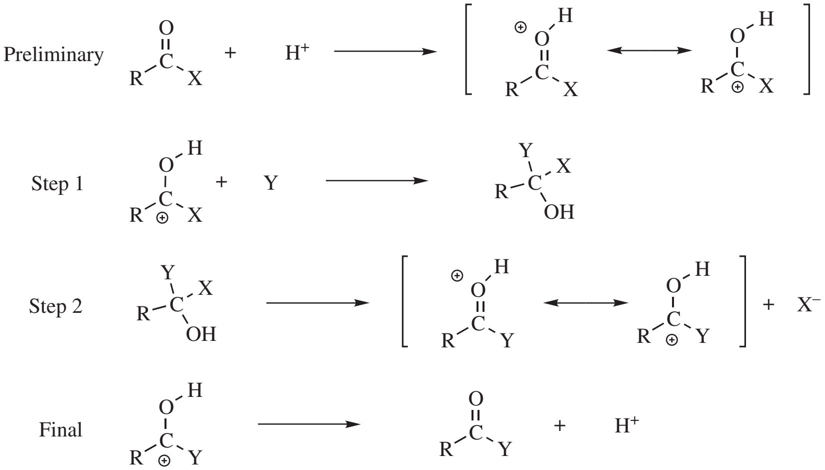
[15]For a review, see Williams, A. *Acc. Chem. Res.* ***1989***, *22*, 387. For examples, see Kevill, D.N.; Foss, F.D. *J. Am. Chem. Soc.* ***1969***, *91*, 5054; Haberfield, P.; Trattner, R.B. *Chem. Commun.* ***1971***, 1481; De Tar, D.F. *J. Am. Chem. Soc.* ***1982***, *104*, 7205; Shpan'ko, I.V.; Goncharov, A.N. *J. Org. Chem. USSR* ***1987***, *23*, 2287; Guthrie, J.P.; Pike, D.C. *Can. J. Chem.* ***1987***, *65*, 1951; Kevill, D.N.; Kim, C. *Bull. Soc. Chim. Fr.* ***1988***, 383, *J. Chem. Soc. Perkin Trans. 2* ***1988***, 1353; Bentley, T.W.; Koo, I.S. *J. Chem. Soc. Perkin Trans. 2* ***1989***, 1385. See, however, Buncel, E.; Um, I.H.; Hoz, S. *J. Am. Chem. Soc.* ***1989***, *111*, 971.

and an SET mechanism has also been reported.[16] However, the tetrahedral mechanism is by far the most prevalent. Although this mechanism displays second-order kinetics, it is not the same as the S_N2 mechanism previously discussed. In the tetrahedral mechanism, first Y attacks to give an intermediate containing both X and Y (**4**), and then X leaves. This sequence, impossible at a saturated carbon, is possible at an unsaturated one because the central carbon can release a pair of electrons to the oxygen and so preserve its octet:



4

When reactions are carried out in acid solution, there may also be a preliminary and a final step:



The hydrogen ion is a catalyst. The reaction rate is increased because it is easier for the nucleophile to attack the carbon when the electron density of the latter has been decreased.[17]

Evidence for the existence of the tetrahedral mechanism is as follows:[18]

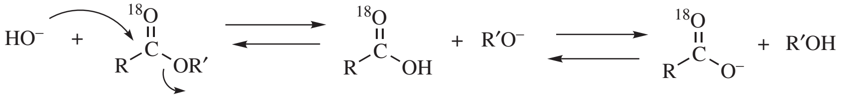
1. The kinetics are first order each in the substrate and in the nucleophile, as predicted by the mechanism.

[16]Bacaloglu, R.; Blaskó, A.; Bunton, C.A.; Ortega, F. *J. Am. Chem. Soc.* ***1990***, *112*, 9336.

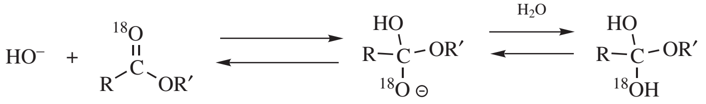
[17]For discussions of general acid and base catalysis of reactions at a carbonyl group, see Jencks, W.P. *Acc. Chem. Res.* ***1976***, *9*, 425; *Chem. Rev.* ***1972***, *72*, 705.

[18]For additional evidence, see Guthrie, J.P. *J. Am. Chem. Soc.* ***1978***, *100*, 5892; Kluger, R.; Chin, J. *J. Am. Chem. Soc.* ***1978***, *100*, 7382; O'Leary, M.H.; Marlier, J.F. *J. Am. Chem. Soc.* ***1979***, *101*, 3300.

2. There is other kinetic evidence in accord with a tetrahedral intermediate. For example, the rate "constant" for the reaction between acetamide and hydroxylamine is not constant, but decreases with increasing hydroxylamine concentration.[19] This is not a smooth decrease; there is a break in the curve. A straight line is followed at low hydroxylamine concentration and another straight line at high concentration. This means that the identity of the rate-determining step is changing. Obviously, this cannot happen if there is only one step: there must be two steps, and hence an intermediate. Similar kinetic behavior has been found in other cases as well,[20] in particular, plots of rate against pH are often bell shaped.
3. Basic hydrolysis has been carried out on carboxylic esters labeled with ^{18}O in the carbonyl group.[21] If this reaction proceeded by the normal S_N2 mechanism, all the ^{18}O would remain in the carbonyl group, even if, in an equilibrium process, some of the carboxylic acid formed went back to the starting material:

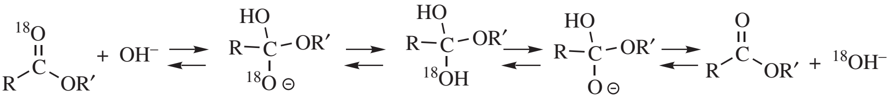


On the other hand, if the tetrahedral mechanism operates



5

then the intermediate **5**, by gaining a proton, becomes converted to the symmetrical intermediate **6**. In this intermediate the OH groups are equivalent, and (except for the small $^{18}O/^{16}O$ isotope effect) either one can lose a proton with equal facility:



5 6 7

The intermediates **5** and **7** can now lose OR′ to give the acid (not shown in the equations given), or they can lose OH to regenerate the carboxylic ester. If **5** goes back to ester, the ester will still be labeled, but if **7** reverts to ester, the

Soc.* ***1964***, *86*, 5697; ***1965***, *87*, 4138; Kevill, D.N.; Johnson, S.L. *J. Am. Chem. Soc.* ***1965***, *87*, 928; Leinhard, G.E.; Jencks, W.P. *J. Am. Chem. Soc.* ***1965***, *87*, 3855; Schowen, R.L.; Jayaraman, H.; Kershner, L.D. *J. Am. Chem. Soc.* ***1966***, *88*, 3373.

[21]Bender, M.L. *J. Am. Chem. Soc.* ***1951***, *73*, 1626; Bender, M.L.; Thomas, R.J. *J. Am. Chem. Soc.* ***1961***, *83*, 4183, 4189.

^{18}O will be lost. A test of the two possible mechanisms is to stop the reaction before completion and to analyze the recovered ester for ^{18}O. This is just what was done by Bender, who found that in alkaline hydrolysis of methyl, ethyl, and isopropyl benzoates, the esters had lost ^{18}O. A similar experiment carried out for acid-catalyzed hydrolysis of ethyl benzoate showed that here too the ester lost ^{18}O. However, alkaline hydrolysis of substituted benzyl benzoates showed *no* ^{18}O loss.[22] This result does not necessarily mean that no tetrahedral intermediate is involved in this case. If **5** and **7** do not revert to ester, but go entirely to acid, no ^{18}O loss will be found even with a tetrahedral intermediate. In the case of benzyl benzoates, this may very well be happening, because formation of the acid relieves steric strain. Another possibility is that **5** loses OR′ before it can become protonated to **6**.[23] Even the experiments that *do* show ^{18}O loss do not *prove* the existence of the tetrahedral intermediate, since it is possible that ^{18}O is lost by some independent process not leading to ester hydrolysis. To deal with this possibility, Bender and Heck[24] measured the rate of ^{18}O loss in the hydrolysis of ethyl trifluorothioloacetate-^{18}O:

This reaction had previously been shown[25] to involve an intermediate by the kinetic methods mentioned on p. 1256. Bender and Heck showed that the rate of ^{18}O loss and the value of the partitioning ratio k_2/k_3 as determined by the oxygen exchange technique were exactly in accord with these values as previously determined by kinetic methods. Thus the original ^{18}O-exchange measurements showed that there is a tetrahedral species present, though not necessarily on the reaction path, while the kinetic experiments showed that there is some intermediate present, though not necessarily tetrahedral. Bender and Heck's results demonstrate that there is a tetrahedral intermediate and that it lies on the reaction pathway.

4. In some cases, tetrahedral intermediates have been isolated[26] or detected spectrally.[27]

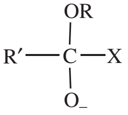
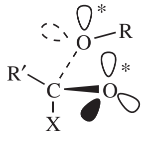
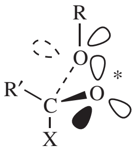
Several studies have been made of the directionality of approach by the nucleophile.[28] Menger has proposed for reactions in general, and specifically for those that proceed by the tetrahedral mechanism, that there is no single definable preferred transition state, but rather a "cone" of trajectories. All approaches within this cone lead to reaction at comparable rates; it is only when the approach comes outside of the cone that the rate falls.



8



A



B

Directionality has also been studied for the second step. Once the tetrahedral intermediate (**4**) is formed, it loses Y (giving the product) or X (reverting to the starting compound). Deslongchamps has proposed that one of the factors affecting this choice is the conformation of the intermediate; more specifically, the positions of the lone pairs. In this view, a leaving group X or Y can depart only if the other two atoms on the carbon both have an orbital antiperiplanar to the C—X or C—Y bond. For example, consider an intermediate **8** formed by attack of $^{-}$OR on a substrate R′COX. Cleavage of the C—X bond with loss of X can take place from conformation **A**, because the two lone-pair orbitals marked * are antiperiplanar to the C—X bond, but not from **B** because only the O^{-} has such an orbital. If the intermediate is in conformation **B**, the OR may leave (if X has a lone-pair orbital in the proper position) rather than X. This factor is called *stereoelectronic control*.[29] Of course, there is free rotation in acyclic intermediates, and many conformations are possible, but some are preferred, and cleavage reactions may take place faster than rotation, so stereoelectronic control can be a factor in some situations. Much evidence has been presented for this concept.[30] More generally, the term *stereoelectronic effects* refers to any case in which orbital

[28]For discussions, see Menger, F.M. *Tetrahedron* ***1983***, *39*, 1013; Liotta, C.L.; Burgess, E.M.; Eberhardt, W.H. *J. Am. Chem. Soc.* ***1984***, *106*, 4849.

[29]It has also been called the "antiperiplanar lone pair hypothesis (ALPH)." For a reinterpretation of this factor in terms of the principle of least nuclear motion (see **15-10**), see Hosie, L.; Marshall, P.J.; Sinnott, M.L. *J. Chem. Soc. Chem.* ***1986***, *64*, 1788; Hegarty, A.F.; Mullane, M. *J. Chem. Soc. Perkin Trans. 2* ***1986***, 995. For evidence against the theory, see Perrin, C.L.; Nuñez, O. *J. Am. Chem. Soc.* ***1986***, *108*, 5997; ***1987***, *109*, 522.

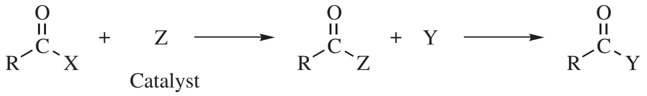
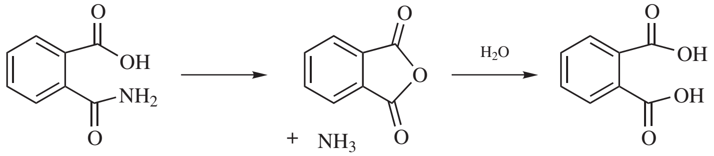
position requirements affect the course of a reaction. The backside attack in the S_N2 mechanism is an example of a stereoelectronic effect.

Some nucleophilic substitutions at a carbonyl carbon are *catalyzed* by nucleophiles.[31] There occur, in effect, two tetrahedral mechanisms:



(For an example, see **16-58**). When this happens internally, we have an example of a neighboring-group mechanism at a carbonyl carbon.[32] For example, the hydrolysis of phthalamic acid (**9**) takes place as follows:



9

Evidence comes from comparative rate studies.[33] Thus **9** was hydrolyzed ~10^5 times faster than benzamide ($PhCONH_2$) at about the same concentration of hydrogen ions. That this enhancement of rate was not caused by the resonance or field effects of COOH (an electron-withdrawing group) was shown by the fact both *o*-nitrobenzamide and terephthalamic acid (the para isomer of **9**) were hydrolyzed more slowly than benzamide. Many other examples of neighboring-group participation at a carbonyl carbon have been reported.[34] It is likely that nucleophilic catalysis is involved in enzyme catalysis of ester hydrolysis.

The attack of a nucleophile on a carbonyl group can result in substitution or addition, though the first step of each mechanism is the same. The main factor that determines the product is the identity of the group X in RCOX. When X is alkyl or hydrogen, addition usually takes place. When X is halogen, OH, OCOR, NH_2, and so on, the usual reaction is substitution.

In both the S_N1 and S_N2 mechanisms, the leaving group departs during the rate-determining step and so directly affects the rate. In the tetrahedral mechanism at a carbonyl carbon, the bond between the substrate and leaving group is still intact during the slow step. Nevertheless, the nature of the leaving group still affects the reactivity in two ways: (*1*) By altering the

TABLE 16.1. The More Important Synthetic Reactions that Take Place by the Tetrahedral Mechanism[a]

Reaction Number	Reaction
16-57	$RCOX + H_2O \longrightarrow RCOOH$
16-58	$RCOOCOR' + H_2O \longrightarrow RCOOH + R'COOH$
16-59	$RCO_2R' + H_2O \longrightarrow RCOOH + R'OH$
16-59	$RCONR'_2 + H_2O \longrightarrow RCOOH + R_2NH$ (R′ = H, alkyl, aryl)
16-61	$RCOX + R'OH \longrightarrow RCO_2R'$
16-62	$RCOOCOR + R'OH \longrightarrow RCO_2R'$
16-63	$RCOOH + R'OH \longrightarrow RCO_2R'$
16-64	$RCO_2R' + R''OH \longrightarrow RCO_2R'' + R'OH$
16-66	$RCOX + R'COO^- \longrightarrow RCOOCOR'$
10-21	$RCOX + H_2O_2 \longrightarrow RCO_3H$
16-69	$RCOX + R'SH \longrightarrow RCOSR'$
16-72	$RCOX + NHR'_2 \longrightarrow RCONR'_2$ (R′ = H, alkyl, aryl)
16-73	$RCOOCOR + NHR'_2 \longrightarrow RCONR'_2$ (R′ = H, alkyl, aryl)
16-74	$RCOOH + NHR'_2 \xrightarrow[\text{agent}]{\text{coupling}} RCONR'_2$ (R′ = H, alkyl, aryl)
16-75	$RCO_2R' + NHR^2 \longrightarrow RCONR^2$ (R^2 = H, alkyl, aryl)
16-79	$RCOOH + SOCl_2 \longrightarrow RCOCl$
19-39	$RCOX + LiAlH(O\text{—}t\text{-Bu})_3 \longrightarrow RCHO$
19-41	$RCONR'_2 + LiAlH_4 \longrightarrow RCHO$
16-81	$RCOX + R_{2'}CuLi \longrightarrow RCOR'$
16-85	$2RCH_2CO_2R' \longrightarrow RCH_2COCHRCO_2R'$

[a]Catalysts are not shown.

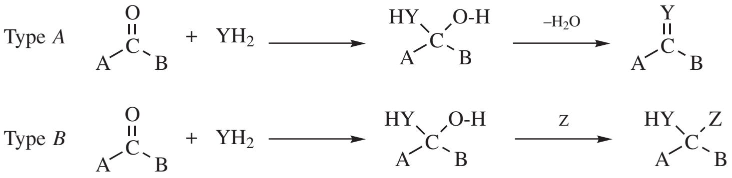
electron density at the carbonyl carbon, the rate of the reaction is affected. The greater the electron-withdrawing character of X, the greater the partial positive charge on C and the more rapid the attack by a nucleophile. (*2*) The nature of the leaving group affects the *position of equilibrium*. In the intermediate **4** (p. 1255), there is competition between X and Y as to which group leaves. If X is a poorer leaving group than Y, then Y will preferentially leave and **4** will revert to the starting compounds. Thus there is a partitioning factor between **4** going on to product (loss of X) or back to starting compound (loss of Y). The sum of these two factors causes the sequence of reactivity to be $RCOCl > RCOOCOR' > RCOOAr > RCOOR' > RCONH_2 > RCONR'_2 > RCOO^-$.[35] Note that this order is approximately the order of decreasing stability of the leaving-group anion. If the leaving group is bulky, it may exert a steric effect and retard the rate for this reason.

For a list of some of the more important reactions that operate by the tetrahedral mechanism, see Table 16.1, which shows the main reactions that proceed by the tetrahedral mechanism.

[35]RCOOH would belong in this sequence just after RCOOAr, but it fails to undergo many reactions for a special reason. Many nucleophiles, instead of attacking the C=O group, are basic enough to take a proton from the acid, converting it to the unreactive $RCOO^-$.

REACTIONS

Many of the reactions in this chapter are simple additions to carbon–hetero multiple bonds, with the reaction ending when the two groups have been added. But in many other cases subsequent reactions take place. We will meet a number of such reactions, but most are of two types:



In type *A*, the initially formed adduct loses water (or, in the case of addition to C=NH, ammonia, etc.), and the net result of the reaction is the substitution of C=Y for C=O (or C=NH, etc.). In type *B*, there is a rapid substitution, and the OH (or NH_2, etc.) is replaced by another group Z, which is often another YH moiety. This substitution is in most cases nucleophilic, since Y usually has an unshared pair and S_N1 reactions occur very well on this type of compound (see p. 482), even when the leaving group is as poor as OH or NH_2. In this chapter, we will classify reactions according to what is initially adding to the carbon–hetero multiple bond, even if subsequent reactions take place so rapidly that it is not possible to isolate the initial adduct.

Most of the reactions considered in this chapter can be reversed. In many cases, we will consider the reverse reactions with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another (e.g., **16-2** and **16-13**). For reactions that are reversible, the principle of microscopic reversibility (p. 309) applies.

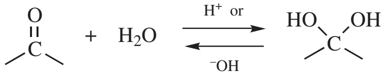
First, we will discuss reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the heteroatom and second reactions in which carbon adds to the heteroatom. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isocyanides, which are different in character, follow. Acyl substitution reactions that proceed by the tetrahedral mechanism, which mostly involve derivatives of carboxylic acids, are treated at the end.

REACTIONS IN WHICH HYDROGEN OR A METALLIC ION ADDS TO THE HETEROATOM

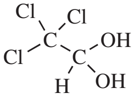
A. Attack by OH (Addition of H_2O)

16-1 The Addition of Water to Aldehydes and Ketones: Formation of Hydrates

O-Hydro-*C*-hydroxy-addition



The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or *gem*-diol.[36] These compounds are usually stable only in water solution and decompose on distillation; that is, the equilibrium shifts back toward the carbonyl compound. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20°C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.[37] It has been found, by exchange with ^{18}O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.[38] Since methyl, a +*I* group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral (trichloroacetaldehyde)[39] is a stable crystalline substance. In order for it to revert to chloral, ^-OH or H_2O must leave; this is made difficult by the electron-withdrawing character of the Cl_3C group. Some other[40] polychlorinated and polyfluorinated



Chloral hydrate

Hydrate of cyclopropanone

aldehydes and ketones[41] and α-keto aldehydes also form stable hydrates, as do cyclopropanones.[42] In the last case,[43] formation of the hydrate relieves some of the *I* strain (p. 399) of the parent ketone.

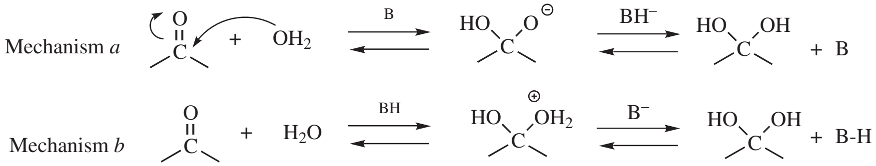
For a review of cyclopropanone chemistry, see Wasserman, H.H.; Clark, G.M.; Turley, P.C. *Top. Curr. Chem.* ***1974***, *47*, 73.

The reaction is subject to both general-acid and general-base catalysis; the following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:[44]



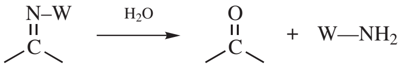
In mechanism *a*, as the H_2O attacks, the base pulls off a proton, and the net result is addition of ^{-}OH. This can happen because the base is already hydrogen bonded to the H_2O molecule before the attack. In mechanism *b*, because HB is already hydrogen bonded to the oxygen of the carbonyl group, it gives up a proton to the oxygen as the water attacks. In this way, B and HB accelerate the reaction even beyond the extent that they form ^{-}OH or H_3O^+ by reaction with water. Reactions in which the catalyst donates a proton to the electrophilic reagent (in this case the aldehyde or ketone) in one direction and removes it in the other are called class e reactions. Reactions in which the catalyst does the same to the nucleophilic reagent are called class n reactions.[45] Thus the acid-catalyzed process here is a class e reaction, while the base catalyzed process is a class n reaction.

For the reaction between ketones and H_2O_2, see **17-37**.

There are no OS references, but see OS **VIII**, 597, for the reverse reaction.

16-2 Hydrolysis of the Carbon-Nitrogen Double Bond[46]

Oxo-de-alkylimino-bisubstitution, and so on



Compounds containing carbon–nitrogen double bonds can be hydrolyzed to the corresponding aldehydes or ketones.[47] For imines (W = R or H) the hydrolysis is easy and can be carried out with water. When W = H, the imine is seldom stable enough for isolation, and in aqueous media hydrolysis usually occurs *in situ*, without isolation. The hydrolysis of Schiff bases (W = Ar) is more difficult and requires

acid or base catalysis. Oximes (W = OH), arylhydrazones (W = NHAr), and, most easily, semicarbazones (W = $NHCONH_2$) can also be hydrolyzed. Often a reactive aldehyde (e.g., formaldehyde) is added to combine with the liberated amine.

A number of other reagents[48] have been used to cleave C=N bonds, especially those not easily hydrolyzable with acidic or basic catalysts or that contain other functional groups that are attacked under these conditions. Oximes have been converted to the corresponding aldehyde or ketone[49] by treatment with, among other reagents, NBS in water,[50] glyoxylic acid (HCOCOOH),[51] Chloramine-T[52] Caro's acid on SiO_2,[53] HCOOH on SiO_2 with microwave irradiation,[54] bromosulfonamides,[55] $SiBr_4$ on wet silica,[56] and $KMnO_4$ on Al_2O_3[57] or on zeolite.[58] Chromate oxidizing agents can be quite effective, including tetraethylammonium permanganate,[59] tetraalkylammonium dichromate with microwave irradiation,[60] pyridinium fluorochromate,[61] quinolinium fluorochromate[62] or dichromate.[63] Alkaline H_2O_2,[64] iodine in acetonitrile,[65] singlet oxygen with NaOMe/MeOH[66] and with an ionic liquids on SiO_2[67] have also been used. Transition-metal compounds have been used, including $SbCl_5$,[68] $Co_2(CO)_8$[69] $Hg(NO_3)_2/SiO_2$,[70] or $BiBr_3$—$Bi(OTf)_3$ in aqueous media,[71] $Bi(NO_3)_3/SiO_2$,[72] a nickel(II) complex

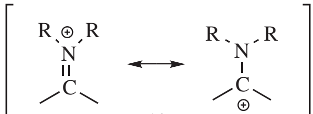
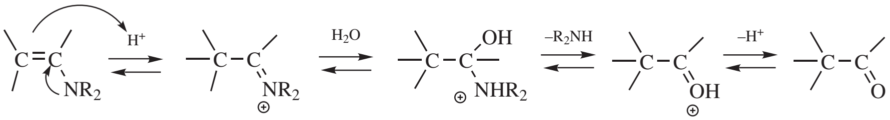
It is thus an example of reaction type *A* (p. 1261). The sequence shown is generalized.[98] In specific cases, there are variations in the sequence of the steps, depending on acid or basic catalysis or other conditions.[99] Which step is rate determining also depends on acidity and on the nature of W and of the groups connected to the carbonyl.[100]



10

Iminium ions (**10**)[101] would be expected to undergo hydrolysis quite readily, since there is a contributing form with a positive charge on the carbon. Indeed, they react with water at room temperature.[102] Acid-catalyzed hydrolysis of enamines (the last step of the Stork reaction, **10-69** involves conversion to iminium ions:[103]



The mechanism of enamine hydrolysis is thus similar to that of vinyl ether hydrolysis (**10-6**).

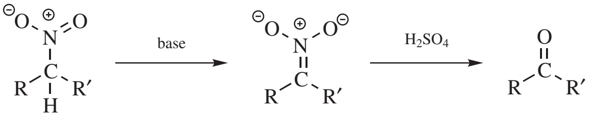
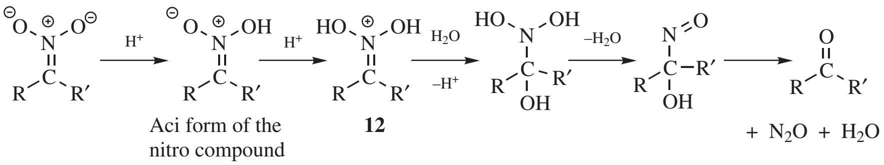
16-3 Hydrolysis of Aliphatic Nitro Compounds

Oxo-de-hydro,nitro-bisubstitution



Primary or secondary aliphatic nitro compounds can be hydrolyzed, respectively, to aldehydes or ketones, by treatment of their conjugate bases with sulfuric acid. This is called the *Nef reaction*.[105] Tertiary aliphatic nitro compounds do not give the reaction because they cannot be converted to their conjugate bases. Like **16-2**, this reaction involves hydrolysis of a C=N double bond. A possible mechanism is[106]



Intermediates of type **12** have been isolated in some cases.[107]

The conversion of nitro compounds to aldehydes or ketones has been carried out with better yields and fewer side reactions by several alternative methods.[108] Among these are treatment of the nitro compound with tin complexes and $NaHSO_3$,[109] activated dry silica gel,[110] or 30% H_2O_2—K_2CO_3,[111] *t*-BuOOH and a catalyst,[112]

DBU in acetonitrile,[113] NaH and $Me_3SiOOSiMe_3$,[114] $NaNO_2$ in aq. DMSO,[115] or ceric ammonium nitrate (CAN).[116] The reaction of Al—$NiCl_2$•6 H_2O in THF converted α,β-unsaturated nitro compounds to the corresponding aldehyde, $PhCH{=}CHNO_2 \rightarrow PhCH_2CHO$.[117]

When *primary* nitro compounds are treated with sulfuric acid without previous conversion to the conjugate bases, they give carboxylic acids. Hydroxamic acids are intermediates and can be isolated, so that this is also a method for preparing them.[118] Both the Nef reaction and the hydroxamic acid process involve the aci form; the difference in products arises from higher acidity, for example, a difference in sulfuric acid concentration from 2 to 15.5 *M* changes the product from the aldehyde to the hydroxamic acid.[119] The mechanism of the hydroxamic acid reaction is not known with certainty, but if higher acidity is required, it may be that the protonated aci form of the nitro compound is further protonated.

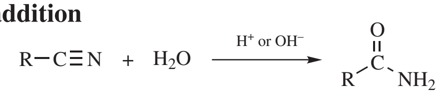
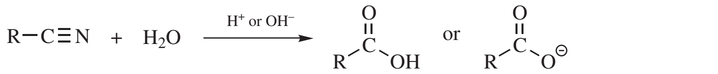
16-4 Hydrolysis of Nitriles

***NN*-Dihydro-*C-oxo*-biaddition**



Hydroxy,oxo-de-nitrilo-tersubstitution



Nitriles can be hydrolyzed to give either amides or carboxylic acids.[120] The amide is formed initially, but since amides are also hydrolyzed with acid or basic treatment, the carboxylic acid is readily formed. When the acid is desired,[121] the reagent of choice is aq. NaOH containing ~6–12% H_2O_2, though acid-catalyzed hydrolysis is also frequently carried out. A "dry" hydrolysis of nitriles has been reported.[122] The hydrolysis of nitriles to carboxylic acids is one of the best methods for the preparation of these compounds. Nearly all nitriles give the reaction, with either acidic or basic catalysts. Hydrolysis of cyanohydrins, RCH(OH)CN, is usually carried out under acidic conditions, because basic solutions cause competing

reversion of the cyanohydrin to the aldehyde and CN^-. However, cyanohydrins have been hydrolyzed under basic conditions with borax or alkaline borates.[123] Enzymatic hydrolysis with *Rhodococcus* sp AJ270 has also been reported.[124] In methanol with BF_3•OEt_2, benzonitrile is converted to methyl benzoate.[125]

There are a number of procedures for stopping at the amide stage,[126] among them the use of concentrated H_2SO_4; 2 equivalents of chlorotrimethylsilane followed by H_2O,[127] aq. NaOH with PEG-400 and microwave irradiation,[128] $NaBO_3$ with 4 equivalents of water and microwave irradiation,[129] heating on neutral alumina,[130] Oxone®,[131] and dry HCl followed by H_2O. The same result can also be obtained by use of water and certain metal ions or complexes;[132] a ruthenium catalyst on alumina with water,[133] MnO_2/SiO_2 with microwave irradiation,[134] $Hg(OAc)_2$ in HOAc;[135] or 2-mercaptoethanol in a phosphate buffer.[136] Nitriles can be hydrolyzed to the carboxylic acids without disturbing carboxylic ester functions also present, by the use of tetrachloro- or tetrafluorophthalic acid.[137] Nitriles are converted to thioamides $ArC(=S)NH_2$ with ammonium sulfide $(NH_4)_2S$ in methanol, with microwave irradiation.[138]

Thiocyanates are converted to thiocarbamates in a similar reaction:[139] $R{-}S{-}C{\equiv}N + H_2O \rightarrow R{-}S{-}C{-}O\ NH_2$. Hydrolysis of cyanamides gives amines, produced by the breakdown of the unstable carbamic acid intermediates: $R_2NCN \rightarrow [R_2NCOOH] \rightarrow R_2NH$.

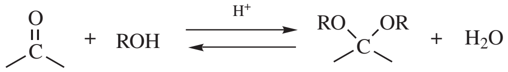
B. Attack by OR or SR (Addition of ROH; RSH)

16-5 The Addition of Alcohols to Aldehydes and Ketones

Dialkoxy-de-oxo-bisubstitution

Dithioalkyl-de-oxo-bisubstitution



Acetals and ketals are formed by treatment of aldehydes and ketones, respectively, with alcohols in the presence of acid catalysts.[140] Lewis acids such as $TiCl_4$[141] $RuCl_3$,[142] or $CoCl_2$[143] can be used in conjunction with alcohols. Dioxolanes have been prepared in ethylene glycol using microwave irradiation and *p*-toluenesulfonic acid as a catalyst.[144] This reaction is reversible, and acetals and ketals can be hydrolyzed by treatment with acid.[145] With small unbranched aldehydes the equilibrium lies to the right. If ketals or acetals of larger molecules must be prepared the equilibrium must be shifted, usually by removal of water. This can be done by azeotropic distillation, ordinary distillation, or the use of a drying agent such as Al_2O_3 or a molecular sieve.[146] The reaction is not catalyzed in either direction by bases, so most acetals and ketals are quite stable to bases, though they are easily hydrolyzed by acids. This reaction is therefore a useful method of protection of aldehyde or ketone functions from attack by bases. The reaction is of wide scope. Most aldehydes are easily converted to acetals.[147] With ketones the process is more difficult, presumably for steric reasons, and the reaction often fails, though many ketals, especially from cyclic ketones, have been made in this manner.[148] Many functional groups may be present without being affected. 1,2-Glycols and 1,3-glycols form cyclic acetals and ketals (1,3-dioxolanes[149]

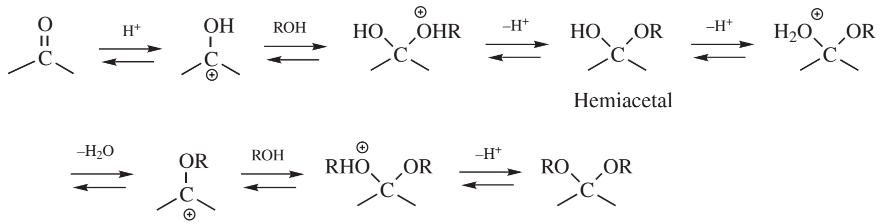
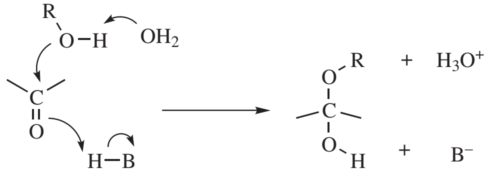
and 1,3-dioxanes,[150] respectively), and these are often used to protect aldehydes and ketones. Chiral dioxolanes have been prepared from chiral diols.[151] Dioxolanes have been prepared from ketones in ionic liquids.[152] Ketones are converted with dimethyl ketals by electrolysis with NaBr in methanol.[153]

Intramolecular reactions are possible in which a keto diol or an aldehyde diol generates a bicyclic ketal or acetal. Fused ring [2.2.0] ketals have been prepared in this manner.[154]

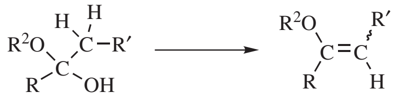
The mechanism, which involves initial formation of a *hemiacetal*,[155] is the reverse of that given for acetal hydrolysis:



In a study of the acid-catalyzed formation of the hemiacetal, Grunwald showed[156] that the data best fit a mechanism in which the three steps shown here are actually all concerted; that is, the reaction is simultaneously catalyzed by acid and base, with water acting as the base:[157]



If the original aldehyde or ketone has an α hydrogen, it is possible for water to split out in that way and enol ethers can be prepared in this manner:



[150]Wu, H.-H.; Yang, F.; Cui, P.; Tang, J.; He, M.-Y. *Tetrahedron Lett.* ***2004***, *45*, 4963; Ishihara, K.; Hasegawa, A.; Yamamoto, H. *Synlett* ***2002***, 1296.

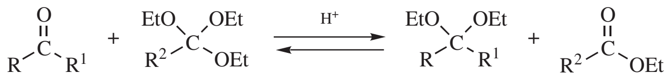
[157]Grunwald also studied the mechanism of the base-catalyzed formation of the hemiacetal, and found it to be the same as that of base-catalyzed hydration (**16-1**, mechanism *a*): Grunwald, E. *J. Am. Chem. Soc.* ***1985***, *107*, 4710. See also, Sørensen, P.E.; Pedersen, K.J.; Pedersen, P.R.; Kanagasabapathy, V.M.; McClelland, R.A. *J. Am. Chem. Soc.* ***1988***, *110*, 5118; Leussing, D.L. *J. Org. Chem.* ***1990***, *55*, 666.

Similarly, treatment with an anhydride and a catalyst can give an enol ester (see **16-6**).[158]

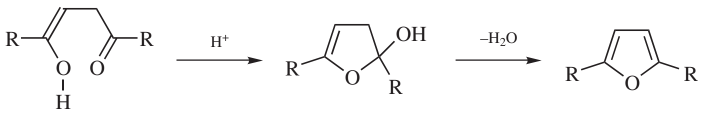
Hemiacetals themselves are no more stable than the corresponding hydrates (**16-1**). As with hydrates, hemiacetals of cyclopropanones[159] and of polychloro and polyfluoro aldehydes and ketones may be quite stable.

When acetals or ketals are treated with an alcohol of higher molecular weight than the one already there, it is possible to get a transacetalation (see **10-13**). In another type of transacetalation, aldehydes or ketones can be converted to acetals or ketals by treatment with another acetal or ketal or with an ortho ester,[160] in the presence of an acid catalyst (shown for an ortho ester):



This method is especially useful for the conversion of ketones to ketals, since the direct reaction of a ketone with an alcohol often gives poor results. In another method, the substrate is treated with an alkoxysilane $ROSiMe_3$ in the presence of trimethylsilyl trifluoromethanesulfonate.[161]

1,4-Diketones give furans when treated with acids. This is actually an example of an intramolecular addition of an alcohol to a ketone, since it is the enol form that adds:



Similarly, 1,5-diketones give pyrans. Conjugated 1,4-diketones, such as 1,4-diphenylbut-2-en-1,4-dione is converted to 2,5-diphenylfuran with formic acid, 5% Pd/C, PEG-200, and a sulfuric acid catalyst with microwave irradiation.[162] Formic acid reacts with alcohols to give orthoformates. Note that alkynyl ketones are converted to furans with palladium (II) acetate.[163]

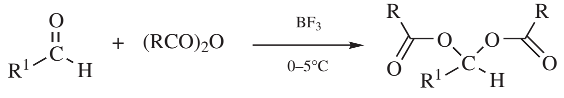
16-6 Acylation of Aldehydes and Ketones

***O*-Acyl-*C*-acyloxy-addition**



Aldehydes can be converted to *acylals* by treatment with an anhydride in the presence of BF_3, proton acids,[164] PCl_3,[165] NBS,[166] $LiBF_4$,[167] $FeCl_3$,[168] $InCl_3$,[169] $InBr_3$,[170] $Cu(OTf)_2$,[171] $Bi(OTf)_3$,[172] $BiCl_3$,[173] $Bi(NO_3)_3$,[174] WCl_6,[175] $ZrCl_4$,[176] ceric ammonium nitrate,[177] With Envirocat EPZ10 and microwave irradiation, acetic anhydride react with aldehydes to give the acylal.[178] Conjugated aldehydes are converted to the corresponding acylal by reaction with acetic anhydride and a $FeCl_3$ catalyst.[179] The reaction cannot normally be applied to ketones, though an exception has been reported when the reagent is trichloroacetic anhydride, which gives acylals with ketones without a catalyst.[180]

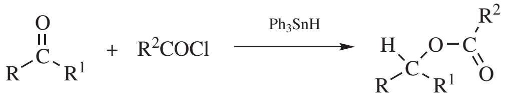
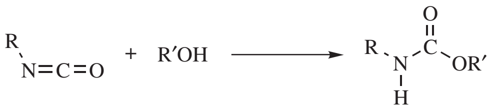
Aldehydes and ketones can be converted to ethers by treatment with an alcohol and triethylsilane in the presence of a strong acid[181] or by hydrogenation in alcoholic acid in the presence of platinum oxide.[182] The process can formally be regarded as addition of ROH to give a hemiacetal, RR′C(OH)OR^2, followed by reduction of the OH. In this respect, it is similar to **16-17**. The reaction of an aldehyde with $BuOSiHMe_2$ and a Me_3SiI catalyst gives the corresponding butyl alkyl ether.[183] In a similar reaction, ketones can be converted to carboxylic esters (reductive acylation of ketones) by treatment with an acyl chloride and triphenyltin hydride.[184]



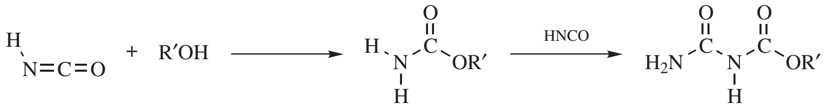
Ethers have also been prepared by the reductive dimerization of two molecules of an aldehyde or ketone (e.g., cyclohexanone → dicyclohexyl ether). This was accomplished by treatment of the substrate with a trialkylsilane and a catalyst.[185]

16-8 The Addition of Alcohols to Isocyanates

N-Hydro-*C*-alkoxy-addition



Carbamates (substituted urethanes) are prepared when isocyanates are treated with alcohols. This is an excellent reaction, of wide scope, and gives good yields. Isocyanic acid HNCO gives unsubstituted carbamates. Addition of a second equivalent of HNCO gives *allophanates*.



Allophanate

The isocyanate can be generated *in situ* by the reaction of an amine and oxalyl chloride, and subsequent reaction with HCl and then an alcohol gives the carbamate.[186] Polyurethanes are made by combining compounds with two NCO groups with

[186]Oh, L.M.; Spoors, P.G.; Goodman, R.M. *Tetrahedron Lett.* ***2004***, *45*, 4769.

compounds containing two OH groups. Cyclic carbamates, such as 1,3-oxazine-2-ones, are generated by the reaction of an isocyanate with an oxetane, in the presence of a palladium catalyst.[187] Isothiocyanates similarly give thiocarbamates[188] RNHCSOR′, though they react slower than the corresponding isocyanates. Isocyanates react with LiAlHSeH and then iodomethane to give the corresponding selenocarbonate (RNHCOSeMe).[189]

The details of the mechanism are poorly understood,[190] though the oxygen of the alcohol is certainly attacking the carbon of the isocyanate. Hydrogen bonding complicates the kinetic picture.[191] The addition of ROH to isocyanates can also be catalyzed by metallic compounds,[192] by light,[193] or, for tertiary ROH, by lithium alkoxides[194] or *n*-butyllithium.[195]

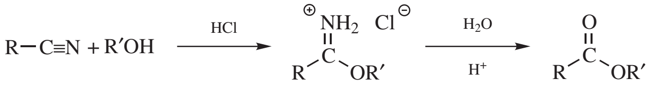
16-9 Alcoholysis of Nitriles

Alkoxy,oxo-de-nitrilo-tersubstitution



The addition of dry HCl to a mixture of a nitrile and an alcohol in the absence of water leads to the hydrochloride salt of an imino ester (imino esters are also called imidates and imino ethers). This reaction is called the *Pinner synthesis*.[196] The salt can be converted to the free imino ester by treatment with a weak base such as sodium bicarbonate, or it can be hydrolyzed with water and an acid catalyst to the corresponding carboxylic ester. If the latter is desired, water may be present from the beginning, in which case aq. HCl can be used and the need for gaseous HCl is eliminated. Imino esters can also be prepared from nitriles with basic catalysts.[197]

[197]Schaefer, F.C.; Peters, G.A. *J. Org. Chem.* ***1961***, *26*, 412.

This reaction is of broad scope and is good for aliphatic, aromatic, and heterocyclic R and for nitriles with oxygen-containing functional groups. The application of the reaction to nitriles containing a carboxyl group constitutes a good method for the synthesis of mono esters of dicarboxylic acids with the desired group esterified and with no diester or diacid present.

Cyanogen chloride reacts with alcohols in the presence of an acid catalyst, such as dry HCl or $AlCl_3$, to give carbamates:[198]

$$ClCN \quad + \quad 2\,ROH \xrightarrow[\text{or}\ AlCl_3]{HCl} ROCONH_2 \quad + \quad RCl$$

ROH can also be added to nitriles in another manner (**16-91**).

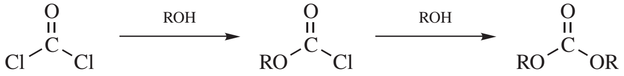
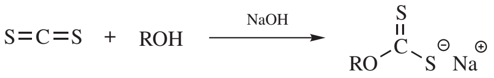
16-10 The Formation of Carbonates and Xanthates

Di-*C*-alkoxy-addition; *S*-Metallo-*C*-alkoxy-addition



The reaction of phosgene with an alcohol generates a haloformic esters, and reaction with a second equivalent of alcohol gives a carbonate. This reaction is related to the acyl addition reactions of acyl chlorides in Reaction **16-98**. An important example is the preparation of carbobenzoxy chloride ($PhCH_2OCOCl$) from phosgene and benzyl alcohol. This compound is widely used for protection of amino groups during peptide synthesis. When an alcohol reacts with certain alkyl halides (e.g., benzyl chloride) and carbon dioxide, in the presence of Cs_2CO_3 and tetrabutylammonium iodide, a mixed carbonate is formed.[199]



The addition of alcohols to carbon disulfide in the presence of a base produces xanthates.[200] The base is often HO^-, but in some cases better results can be obtained by using methylsulfinyl carbanion $MeSOCH_2^-$.[201] If an alkyl halide RX is present, the xanthate ester ROCSSR′ can be produced directly. In a similar manner, alkoxide ions add to CO_2 to give carbonate ester salts ($ROCOO^-$).

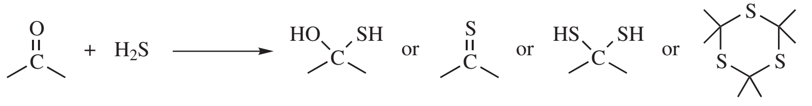
C. Sulfur Nucleophiles

16-11 The Addition of H_2S and Thiols to Carbonyl Compounds

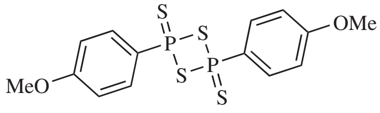
O-Hydro-*C*-mercapto-addition[202]



13 14 15 16

The addition of H_2S to an aldehyde or ketone can result in a variety of products. The most usual product is the trithiane **16**.[203] *gem*-Dithiols (**15**) are much more stable than the corresponding hydrates or α-hydroxy thiols.[204] They have been prepared by the treatment of ketones with H_2S under pressure[205] and under mild conditions with HCl as a catalyst.[206] Thiols add to aldehydes and ketones to give hemimercaptals, CH(OH)SR and dithioacetals, $CH(SR)_2$ (**16-5**). α-Hydroxy thiols (**13**) can be prepared from polychloro and polyfluoro aldehydes and ketones.[207] Apparently **13** are stable only when prepared from these compounds, and not even for all of them.

Thioketones[2] (**14**) can be prepared from certain ketones, such as diaryl ketones, by treatment with H_2S and an acid catalyst, usually HCl. They are often unstable and usually trimerize (to **16**) or react with air. Thioaldehydes[208] are even less stable and simple ones[209] apparently have never been isolated, though *t*-BuCHS has been prepared in



17

[202]This name applies to formation of **13**. Names for formation of **14**–**16**, are, respectively, thioxo-de-oxo-bisubstitution, dimercapto-de-oxo-bisubstitution, and carbonyl–trithiane transformation.

solution, where it exists for several hours at 20°C.[210] A high-yield synthesis of thioketones involves treatment of acyclic[211] ketones with 2,4-bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane-2,4-disulfide **9**[212] (known as *Lawesson's reagent*)[213]. Thioketones can also be prepared by treatment of ketones with P_4S_{10},[214] P_4S_{10} and hexamethyldisiloxane,[215] P_4S_{10} on alumina,[216] or $CF_3SO_3SiMe_3/S(SiMe_3)_2$,[217] and from oximes or various types of hydrazone (overall conversion $C{=}N^{-} \rightarrow C{=}S$).[218] Reagent **17** converts the C=O groups of amides and carboxylic esters[219] to C=S groups.[220] Similarly, $POCl_3$ followed by $S(TMS)_2$ converts lactams to thiolactams[221] and treatment with triflic anhydride, and then H_2S converts amides to thioamides.[222] The reaction of an amide with triflic anhydride, and then aq. $S(NH_4)_2$ gives the corresponding thioamide.[223] The $H_2S{-}Me_3SiCl{-}(i\text{Pr})_2NLi$ complex converts carboxylic esters to thiono esters.[224] Lactones react with **9** in the presence of hexamethyldisiloxane an microwave irradiation to give the thiolactone.[225] Carboxylic acids (RCOOH) can be converted directly to dithiocarboxylic esters (RCSSR′)[226] in moderate yield, with P_4S_{10} and a primary alcohol (R′OH).[227]

Thiols add to aldehydes and ketones to give hemimercaptals and dithioacetals. Hemimercaptals are ordinarily unstable,[228] though they are more stable than the corresponding hemiacetals and can be isolated in certain cases.[229] Dithioacetals,

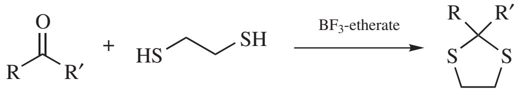
like acetals, are stable in the presence of bases, except that a strong base can remove the aldehyde proton, if there is one[230] (see **10-71**).



18

The reaction of aldehydes or ketones with thiols, usually with a Lewis acid catalyst, leads to dithioacetals[231] or dithioketals. The most common catalyst used is probably boron trifluoride etherate (BF_3•OEt_2).[232] Similarly reactions that use 1,2-ethanedithiol or 1,3-propanedithiol lead to 1,3-dithiolanes, such as **18**[233] or 1,3-dithianes.[234] Dithioacetals can also be prepared from aldehydes or ketones by treatment with thiols in the presence of $TiCl_4$,[235] $SiCl_4$,[236] $LiBF_4$,[237] $Al(OTf)_3$,[238] with a disulfide RSSR (R = alkyl or aryl),[239] or with methylthiotrimethylsilane ($MeSSiMe_3$).[240]

Dithioacetals and dithioketals are used as protecting groups for aldehydes and ketones, and after subsequent reactions involving the R or R′ group, the protecting group can then be removed.[241] There are a variety of reagents that convert these compounds back to the carbonyl.[242] Simple hydrolysis is the most common method for converting thiocarbonyls to carbonyls. Stirring thioketones with 4-nitrobenzaldehyde and a catalytic amount of TMSOTf gives the ketone.[243] The reaction of a thioketone and Clayfen with microwave irradiation give the ketone.[244] Thioamides

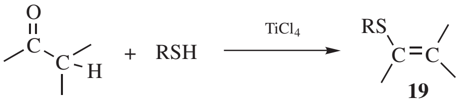
are converted to amides with Caro's acid on SiO_2.[245] Lewis acids, such as aluminum chloride ($AlCl_3$) and mercuric salts, are common reagents and their use is referred to as the Corey–Seebach procedure.[246] Other reagents include BF_3•OEt_2 in aq. THF containing mercuric oxide (HgO),[247] NBS,[248] iodine in DMSO,[249] ceric ammonium nitrate, $Ce(NH_4)_2(NO_3)_6$,[250] iodomethane in aqueous media,[251] Clayfen with microwave irradiation,[252] $PhI(OAc)_2$ in aqueous acetone,[253] and NCS with silver nitrate in aqueous acetonitrile.[254] When aldehydes and ketones react with mercapto-alcohols, mixed acetals or ketals are formed. The use of 2-mercaptoethanol ($HSCH_2CH_2OH$), for example, leads to an oxathiolane[255] and 3-mercaptopropanol ($HSCH_2CH_2CH_2OH$) leads to an oxathiane. Alternatively, the dithioketal can be desulfurized with Raney nickel (**14-27**), giving the overall conversion $C{=}O \rightarrow CH_2$.



19

If an aldehyde or ketone possesses an α hydrogen, it can be converted to the corresponding enol thioether (**19**) by treatment with a thiol in the presence of $TiCl_4$.[256] Aldehydes and ketones have been converted to sulfides by treatment with thiols and pyridine–borane, $RCOR' + R^2SH \rightarrow RR'CHSR^2$,[257] in a reductive alkylation reaction, analogous to **16-7**.

Bisulfite addition products are formed from aldehydes, methyl ketones, cyclic ketones (generally seven-membered and smaller rings), α-keto esters, and isocyanates, upon treatment with sodium bisulfite. Most other ketones do not undergo the reaction, probably for steric reasons. The reaction is reversible (by treatment of the addition product with either acid or base[258])[259] and is useful for the purification of the starting compounds, since the addition products are soluble in water and many of the impurities are not.[260]

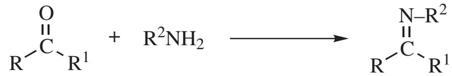
16-13 The Addition of Amines to Aldehydes and Ketones

Alkylimino-de-oxo-bisubstitution



The addition of ammonia[261] to aldehydes or ketones does not generally give useful products. According to the pattern followed by analogous nucleophiles, the initial products would be expected to be *hemiaminals*,[262] but these compounds are generally unstable. Most imines with a hydrogen on the nitrogen spontaneously polymerize.[263] In the presence of an oxidizing agent, such a MnO_2 (see **19-3**), primary alcohols can be converted to imines.[264]

In contrast to ammonia, primary, secondary, and tertiary amines can add to aldehydes[265] and ketones to give different kinds of products. Primary amines give imines[266] and secondary amines gives enamines (**10-69**). This section will focus on imines. Reduction of ω-azido ketones leads to the amino-ketones, which cyclizes to form a 2-substituted pyrroline.[267] Reduction of nitro-ketones in the presence

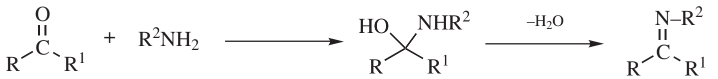
[267]Prabhu, K.P.; Sivanand, P.S.; Chandrasekaran, S. *Synlett* ***1998***, 47.

of ruthenium compounds and CO also leads to 1-substituted pyrrolines.[268] In contrast to imines in which the nitrogen is attached to a hydrogen, these imines are stable enough for isolation. However, in some cases, especially with simple R groups, they rapidly decompose or polymerize unless there is at least one aryl group on the nitrogen or the carbon. When there is an aryl group, the compounds are quite stable. They are usually called *Schiff bases*, and this reaction is the best way to prepare them.[269] The reaction is straightforward and proceeds in high yields. Even sterically hindered imines can be prepared.[270] Both imines and enamines (see below) have been prepared on clay with microwave irradiation.[271] The initial *N*-substituted hemiaminals[272] lose water to give the stable Schiff bases:



In general, ketones react more slowly than aldehydes, and higher temperatures and longer reaction times are often required.[273] In addition, the equilibrium must often be shifted, usually by removal of the water, either azeotropically by distillation, or with a drying agent, such as $TiCl_4$,[274] or with a molecular sieve.[275] Imines have been formed from aldehydes and amines in an ionic liquid.[276]

The reaction is often used to effect ring closure.[277] The *Friedländer quinoline synthesis*[278] is an example where ortho alkenyl aniline derivatives give the quinoline, **20**.[279] The alkene derivative can be prepared *in situ* from an aldehyde and a suitably functionalized ylid.[280]

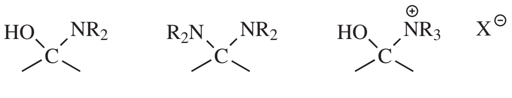
Pyrylium ions react with ammonia or primary amines to give pyridinium ions[281] (see p. 498). Primary amines react with 1,4-diketones, with microwave irradiation, to give *N*-substituted pyrroles.[282] Similar reactions in the presence of Montmorillonite KSF[283] or by simply heating the components with tosic acid[284] have been reported.

As mentioned, the reaction of secondary amines with ketones leads to enamines (**10-69**). When secondary amines are added to aldehydes or ketones, the initially formed *N,N*-disubstituted hemiaminals (**21**) cannot lose water in the same way, and in some cases it is possible to isolate them.[285] However, they are generally unstable, and under the reaction conditions usually react further. If no α hydrogen is present, **10** is converted to



21 **22** (aminal) **23**

the more stable *aminal* (**22**).[286] However, if an α hydrogen is present, water (from **21**) or RNH_2 (from **22**) can be lost in that direction to give an enamine, **24**.[287] This is the most common method[288] for the preparation of enamines and usually takes place when an aldehyde or ketone containing an α hydrogen is treated with a secondary amine. The water is usually removed azeotropically or with a drying agent,[289] but molecular sieves can also be used.[290] Silyl carbamates, such as $Me_2NCO_2SiMe_3$, have been used to convert ketones to enamines.[291] Stable primary enamines have also been prepared.[292] Enamino-ketones have been prepared from diketones and secondary amines using low molecular weight amines in water,[293] or using microwave irradiation on silica gel.[294] Secondary amine perchlorates react

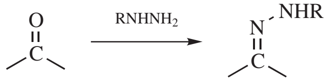
16-14 The Addition of Hydrazine Derivatives to Carbonyl Compounds

Hydrazono-de-oxo-bisubstitution



The product of condensation of a hydrazine and an aldehyde or ketone is called a *hydrazone*. Hydrazine itself gives hydrazones only with aryl ketones. With other aldehydes and ketones, either no useful product can be isolated, or the remaining NH_2 group condenses with a second equivalent of carbonyl compound to give an *azine*. This type of product is especially important for aromatic aldehydes:

$$ArCH{=}N{-}NH_2 \quad + \quad ArCHO \longrightarrow ArCH{=}N{-}N{=}CHAr$$ An azine

However, in some cases azines can be converted to hydrazones by treatment with excess hydrazine and NaOH.[300] Arylhydrazines, especially phenyl, *p*-nitrophenyl, and 2,4-dinitrophenyl,[301] are used much more often and give the corresponding hydrazones with most aldehydes and ketones.[302] Since these are usually solids, they make excellent derivatives and are commonly employed for this purpose. Cyclic hydrazones are also known,[303] as are conjugated hydrazones.[304] Azides react

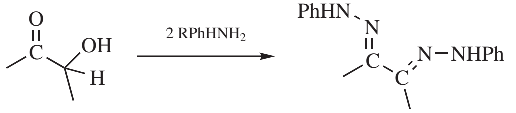
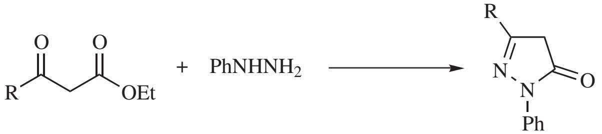
with *N,N*-dimethylhydrazine and ferric chloride to give the *N,N*-dimethylhydrazone.[305] Alkenes react with CO/H_2, phenylhydrazine and a diphosphine catalyst to give a regioisomeric mixture of phenylhydrazones that favored "anti-Markovnikov" addition.[306] Oximes are converted to hydrazones with water and hydrazine in refluxing ethanol.[307]

α-Hydroxy aldehydes and ketones and α-dicarbonyl compounds give *osazones*, in which two adjacent carbons have carbon–nitrogen double bonds:



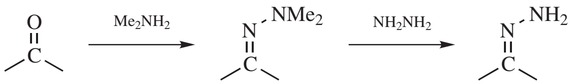
Osazones are particularly important in carbohydrate chemistry. In contrast to this behavior, β-diketones and β-keto esters give *pyrazoles* and *pyrazolones*, respectively (illustrated for β-keto esters):



Other hydrazine derivatives frequently used to prepare the corresponding hydrazone are semicarbazide $NH_2NHCONH_2$, in which case the hydrazone is called a semicarbazone, and *Girard's reagents T and P*, in which case the hydrazone is water soluble because of the ionic group. Girard's reagents are often used for purification of carbonyl compounds.[308]

Girard's reagent T Girard's reagent P

Simple *N*-unsubstituted hydrazones can be obtained by an exchange reaction. The *N,N*-dimethylhydrazone is prepared first, and then treated with hydrazine:[309]



No azines are formed under these conditions.

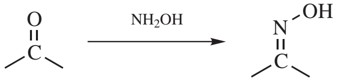
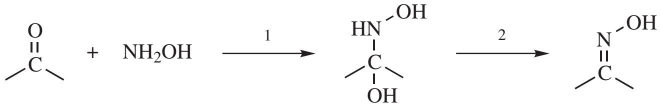
16-15 The Formation of Oximes

Hydroxyimino-de-oxo-bisubstitution



In a reaction very much like **16-14**, oximes can be prepared by the addition of hydroxylamine to aldehydes or ketones. Derivatives of hydroxylamine [e.g., H_2NOSO_3H and $HON(SO_3Na)_2$] have also been used. For hindered ketones, such as hexamethylacetone, high pressures (as high as 10,000 atm) may be necessary.[310] The reaction of hydroxylamine with unsymmetrical ketones or with aldehydes leads to a mixture of (*E*)- and (*Z*)-isomers. For aromatic aldehydes, heating with K_2CO_3 led to the (*E*)- isomer whereas heating with $CuSO_4$ gave the (*Z*)-hydroxylamine.[311] Hydroxylamines react with ketones in ionic liquids[312] and on silica gel.[313]

It has been shown[314] that the rate of formation of oximes is at a maximum at a pH that depends on the substrate but is usually ~4, and that the rate decreases as the pH is either raised or lowered from this point. We have previously seen (p. 1256) that bell-shaped curves like this are often caused by changes in the rate-determining step. In this case, at low pH values step 2 is rapid (because it is acid-catalyzed), and step 1



25

is slow (and rate-determining), because under these acidic conditions most of the NH_2OH molecules have been converted to the conjugate NH_3OH^+ ions, which cannot attack the substrate. As the pH is slowly increased, the fraction of free NH_2OH molecules increases and consequently so does the reaction rate, until the maximum rate is reached at ~pH 4. As the rising pH has been causing an increase in the rate of step 1, it has also been causing a *decrease* in the rate of the acid-catalyzed step 2, although this latter process has not affected the overall rate since step 2 was still faster than step 1. However, when the pH goes above ~4, step 2 becomes rate-determining, and although the rate of step 1 is still increasing (as it will until essentially all the NH_2OH is unprotonated), it is now

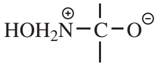
step 2 that determines the rate, and this step is slowed by the decrease in acid concentration. Thus the overall rate decreases as the pH rises beyond ~4. It is likely that similar considerations apply to the reaction of aldehydes and ketones with amines, hydrazines, and other nitrogen nucleophiles.[315] There is evidence that when the nucleophile is 2-methylthiosemicarbazide, there is a second change in the rate-determining step: above pH ~10 *basic* catalysis of step 2 has increased the rate of this step to the point where step 1 is again rate determining.[316] Still a third change in the rate-determining step has been found at about pH 1, showing that at least in some cases step 1 actually consists of two steps: formation of a zwitterion, for example,



in the case shown above, and conversion of this to **25**.[317] The intermediate **25** has been detected by nmr in the reaction between NH_2OH and acetaldehyde.[318]

In another type of process, oximes can be obtained by passing a mixture of ketone vapor, NH_3, and O_2 over a silica-gel catalyst.[319] Ketones can also be converted to oximes by treatment with other oximes, in a transoximation reaction.[320]

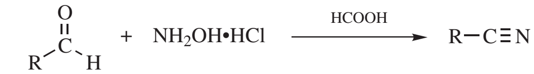
16-16 The Conversion of Aldehydes to Nitriles

Nitrilo-de-hydro,oxo-tersubstitution



Aldehydes can be converted to nitriles in one step by treatment with hydroxylamine hydrochloride and either formic acid,[321] $NaHSO_4$•SiO_2 with microwave irradiation,[322] or $(Bu_4N)_2S_2O_8$ with $Cu(HCO_2)$•$Ni(COOH)_2$ and aq. KOH.[323] Heating in NMP is also effective with aryl aldehydes[324] and heating on dry alumina with

aliphatic aldehyde.[325] The reaction is a combination of **16-15** and **17-29**. Direct nitrile formation has also been accomplished with certain derivatives of NH_2OH, notably, NH_2OSO_2OH.[326] Treatment with hydroxylamine and NaI[327] or certain carbonates[328] also converts aldehydes to the nitrile. Another method involves treatment with hydrazoic acid, though the Schmidt reaction (**18-16**) may compete.[329] Aromatic aldehydes have been converted to nitriles in good yield with $NH_2OH/HCOOH$ on silica gel.[330] Microwave irradiation has been used with NH_2OH•HCl and another reagent, which includes phthalic anhydride,[331] Bu_2SnO•Al_2O_3,[332] or H—Y zeolite.[333] Other reagents include *N*-phenylurea with tosic acid,[334] MnO_2 and ammonia,[335] I_2 with aqueous ammonia,[336] dimethylhydrazine followed by dimethyl sulfoxide,[337] trimethylsilyl azide,[338] and with hydroxylamine hydrochloride, $MgSO_4$, and TsOH.[339] The reaction of a conjugated aldehyde with ammonia, CuCl and 50% H_2O_2 gave the conjugated nitrile.[340] Benzylic alcohols can be oxidized in the presence of ammonia to give the nitrile.[341] Trichloroisocyanuric acid with a catalytic amount of TEMPO (p. 274) converts aldehydes to nitriles at 0°C in dichloromethane.[342]

On treatment with 2 equivalents of dimethylaluminum amide Me_2AlNH_2, carboxylic esters can be converted to nitriles: $RCOOR' \rightarrow RCN$.[343] This is very likely a combination of **16-75** and **17-30**. See also, **19-5**.

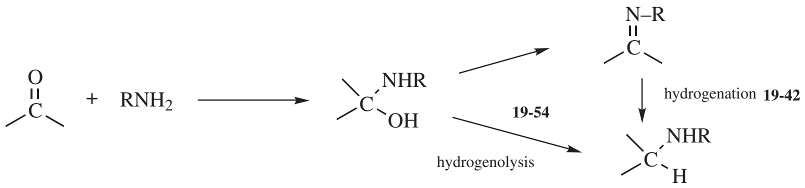
When an aldehyde or a ketone is treated with ammonia or a primary or secondary amine in the presence of hydrogen and a hydrogenation catalyst (heterogeneous or homogeneous),[344] *reductive alkylation* of ammonia or the amine (or *reductive amination* of the carbonyl compound) takes place.[345] The reaction can formally be regarded as occurring in the following manner (shown for a primary amine), which probably does correspond to the actual sequence of steps:[346] In this regard, the reaction of an aldehyde with an amine to give an iminium salt (**16-31**) can be followed in a second chemical step of reduction of the C=N unit (**19-42**) using $NaBH_4$ or a variety of other reagents.[347]



Primary amines have been prepared from many aldehydes with at least five carbons and from many ketones by treatment with ammonia and a reducing agent. Smaller aldehydes are usually too reactive to permit isolation of the primary amine. Secondary amines have been prepared by both possible procedures: 2 equivalents of ammonia and 1 equivalent of aldehyde or ketone, and 1 equivalent of primary amine and 1 equivalent of carbonyl compound, the latter method being better for all but aromatic aldehydes. Tertiary amines can be prepared in three ways, but the method is seldom carried out with 3 equivalents of ammonia and 1 equivalent of carbonyl compound. Much more often they are prepared from primary or secondary amines.[348] When the reagent is ammonia, it is possible for the initial product to react again and for this product to react again, so that secondary and tertiary amines are usually obtained as side products. Similarly, primary amines give tertiary as well as secondary amines. In order to minimize this, the aldehyde or ketone is treated with an excess of ammonia or primary amine (unless of course the higher amine is desired).

For ammonia and primary amines there are two possible pathways, but when secondary amines are involved, only the hydrogenolysis pathway is possible. The reaction is compatible with amino acids, giving the *N*-alkylated amino acid.[349]

Other reducing agents[350] can be used instead of hydrogen and a catalyst, among them zinc and HCl, $B_{10}H_{14}$[351] or $B_{10}H_{14}$ with Pd/C,[352] a picolinyl borane complex in acetic acid–methanol,[353] $PhSiH_3$ with 2% Bu_2SnCl_2,[354] and polymethylhydrosiloxane.[355] Several hydride reducing agents can be used, including $NaBH_4$[356] sodium borohydride with $Ti(OiPr)_4$[357] or $NiCl_2$,[358] $NaBH_4/H_3BO_4$,[359] borohydride-exchange resin,[360] sodium cyanoborohydride ($NaBH_3CN$),[361] sodium triacetoxyborohydride,[362] or a polymer-bound triethylammonium acetoxyborohydride.[363] A Hantzsch dihydropyridine in conjunction with a scandium catalyst has been used.[364] An interesting variation uses a benzylic alcohol in a reaction with a primary amine, and a mixture of MnO_2 and $NaBH_4$, giving *in situ* oxidation to the aldehyde and reductive amination to give the amine as the final product.[365]

Formic acid is commonly used for reductive amination[366] in what is called the *Wallach reaction*. Secondary amines react with formaldehyde and NaH_2PO_3 to give the *N*-methylated tertiary amine[367] and microwave irradiation has also been used.[368] Conjugated aldehydes are converted to alkenyl-amines with the amine/silica gel followed by reduction with zinc borohydride.[369] In the particular case where primary or secondary amines are reductively methylated with formaldehyde and formic acid, the method is called the *Eschweiler–Clarke procedure*. Heating with paraformaldehyde and oxalyl chloride has been used to give the same result.[370] It is

possible to use ammonium (or amine) salts of formic acid,[371] or formamides, as a substitute for the Wallach conditions. This method is called the *Leuckart reaction*,[372] and in this case the products obtained are often the *N*-formyl derivatives of the amines instead of the free amines. A transition-metal catalyzed variation has been reported.[373] Primary and secondary amines can be *N*-ethylated (e.g., ArNHR → ArNREt) by treatment with $NaBH_4$ in acetic acid.[374] Aldehydes react with aniline in the presence of Montmorillonite K10 clay and microwaves to give the amine.[375] Tributyltin hydride is used with an ammonium salt,[376] or Bu_2SnClH•HMPA with an aromatic amine,[377] in the presence of a ketone to give the corresponding amine. Allylic silanes react with aldehydes and carbamates, in the presence of bismuth catalysts,[378] or BF_3•OEt_2[379] to give the corresponding allylic *N*-carbamoyl derivative, and trityl perchlorate has been used for the same purpose when *N*-trimethylsilyl carbamates are employed.[380] The reaction can be done with aromatic amines in the presence of vinyl ethers and a copper complex to give β-amino ketones.[381] Reductive amination of an aryl amine and an aryl aldehyde that contains a ortho conjugated ketone substituents gives the amine, which adds 1,4- (**15-AA**) to the α,β-unsaturated ketone unit to give a bicyclic amine.[382] Alternative methods of reductive alkylation have been developed. Alkylation of an imine formed *in situ* is also possible.[383]

Reductive alkylation has also been carried out on nitro, nitroso, azo, and other compounds that are reduced *in situ* to primary or secondary amines. Azo compounds react with aldehydes, in the presence of proline, and subsequent reduction with $NaBH_4$ gives the chiral hydrazine derivative.[384]

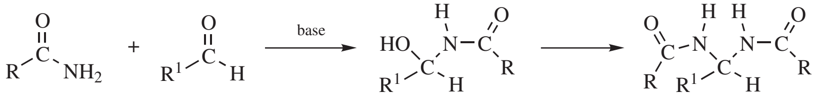
16-18 Addition of Amides to Aldehydes

Alkylamido-de-oxo-bisubstitution

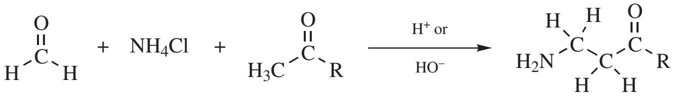


Amides can add to aldehydes in the presence of bases (so the nucleophile is actually $RCONH^-$) or acids to give acylated amino alcohols, which often react further to give alkylidene or arylidene bisamides.[385] If the R′ group contains an α hydrogen, water may split out.

Sulfonamides add to aldehydes to give the *N*-sulfonyl imine. Benzaldehyde reacts with $TsNH_2$, for example, at 160°C in the presence of $Si(OEt)_4$,[386] with trifluoroacetic anhydride (TFAA) in refluxing dichloromethane,[387] or with $TiCl_4$ in refluxing dichloroethane,[388] to give the *N*-tosylimine, Ts—N=CHPh. In a similar manner, the reaction of $TolSO_2Na + PhSO_2Na$ with an aldehyde in aqueous formic acid gives the *N*-phenylsulfonyl imine.[389] The reaction of an aldehyde with $Ph_3P{=}NTs$ and a ruthenium catalyst gives the *N*-tosyl imine.[390] Reaction of aldehydes with $LiAl(NHBn)_4$ also give the corresponding *N*-benzylimine.[391]

16-19 The Mannich Reaction

Acyl,amino-de-oxo-bisubstitution, and so on



In the *Mannich reaction*, formaldehyde (or sometimes another aldehyde) is condensed with ammonia, in the form of its salt, and a compound containing an active hydrogen.[392] This can formally be considered as an addition of ammonia to give

H_2NCH_2OH, followed by a nucleophilic substitution. Instead of ammonia, the reaction can be carried out with salts of primary or secondary amines,[393] or with amides,[394] in which cases the product is substituted on the nitrogen with R, R_2, and RCO, respectively. The imine can be generated *in situ*, and the reaction of a ketone, formaldehyde, and diethylamine with microwave irradiation gave the Mannich product, a β-amino ketone.[395] Arylamines do not normally give the reaction. Hydrazines can be used.[396] The product is referred to as a *Mannich base*. Many active hydrogen compounds give the reaction, including ketones and aldehydes, esters, nitroalkanes,[397] and nitriles as well as ortho-carbons of phenols, the carbon of terminal alkynes, the oxygen of alcohols and the sulfur of thiols.[398] Vinylogous Mannich reactions are known.[399]

The Mannich base can react further in three ways. If it is a primary or secondary amine, it may condense with one or two additional molecules of aldehyde and active compound, for example,

$$H_2NCH_2CH_2COR \xrightarrow[CH_3COR]{HCHO} HN(CH_2CH_2COR)_2 \xrightarrow[CH_3COR]{HCHO} N(CH_2CH_2COR)_3$$

If the active hydrogen compound has two or three active hydrogens, the Mannich base may condense with one or two additional molecules of aldehyde and ammonia or amine, for example,

$$H_2NCH_2CH_2COR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_2CHCOR \xrightarrow[NH_3]{HCHO} (H_2NCH_2)_3CHCOR$$

Another further reaction consists of condensation of the Mannich base with excess formaldehyde:

$$H_2NCH_2CH_2COR + HCHO \longrightarrow H_2C{=}NCH_2CH_2COR$$

Sometimes it is possible to obtain these products of further condensation as the main products of the reaction. At other times they are side products.

When the Mannich base contains an amino group β to a carbonyl (and it usually does), ammonia is easily eliminated. This is a route to α,β-unsaturated aldehydes, ketones, esters, and so on.

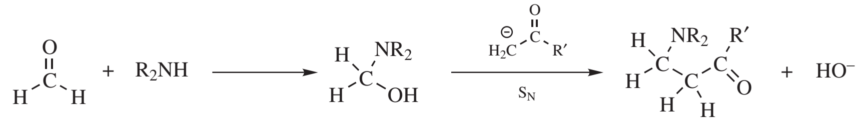
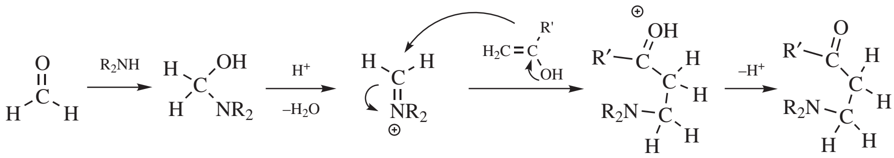
Studies of the reaction kinetics have led to the following proposals for the mechanism of the Mannich reaction.[400]

The base-catalyzed reaction:



The acid-catalyzed reaction:



26

According to this mechanism, it is the free amine, not the salt that reacts, even in acid solution; and the active-hydrogen compound (in the acid-catalyzed process) reacts as the enol when that is possible. This latter step is similar to what happens in **12-4**. There is kinetic evidence for the intermediacy of the iminium ion (**26**).[401]

When an unsymmetrical ketone is used as the active-hydrogen component, two products are possible. Regioselectivity has been obtained by treatment of the ketone with pre-formed iminium ions:[402] the use of $Me_2N^+{=}CH_2\ CF_3COO^{\ominus}$ in CF_3COOH gives substitution at the more highly substituted position, while with $(i\text{Pr})_2N{=}CH_2^+\ ClO_4^{\ominus}$ the reaction takes place at the less highly substituted position.[403] The pre-formed iminium compound dimethyl(methylene)ammonium iodide $CH_2{=}N^+Me_2\ I^{\ominus}$, called *Eschenmoser's salt*,[404] has also been used in Mannich reactions.[405] The analogous chloride salt has been condensed with an imine to give and a β,β′-dimethylamino ketone after acid hydrolysis.[406]

Another type of pre-formed reagent (**28**) has been used to carry out diastereoselective Mannich reactions. The lithium salts **27** are treated with $TiCl_4$ to give **28**, which is then treated with the enolate of a ketone.[407] The palladium catalyzed Mannich reaction of enol ethers to imines is also known.[408] The reaction of silyl enol ethers and imines is catalyzed by HBF_4 in aqueous methanol.[409] Similarly, silyl enol ethers react with aldehydes and aniline in the presence of $InCl_3$ to give the β-amino ketone.[410] Imines react on Montmorillonite K10 clay and microwave irradiation gives β-amino esters.[411] Enol ethers react similarly in the presence of $Yb(OTf)_3$.[412]

Enantioselective Mannich reactions are known.[413] The most common method uses a chiral catalyst, including proline,[414] proline derivatives or proline analogs.[415] Chiral diamine[416] or phosphine-imine[417] ligands have been used. Chiral auxiliaries on the carbonyl fragment can be used.[418] Chiral imines, in the form of chiral hydrazones have been used with silyl enol ethers and a scandium catalyst.[419] Chiral amine react with aldehydes, with silyl enol ethers and an $InCl_3$ catalyst in ionic liquids, to give the Mannich product with good enantioselectivity.[420]

Ammonia and primary and secondary amines can be added to isocyanates[421] to give substituted ureas.[422] Isothiocyanates give thioureas.[423] This is an excellent method for the preparation of ureas and thioureas, and these compounds are often used as derivatives for primary and secondary amines. Isocyanic acid (HNCO) also gives the reaction; usually its salts (e.g., NaNCO) are used. Wöhler's famous synthesis of urea involved the addition of ammonia to a salt of this acid.[424]

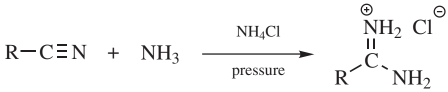
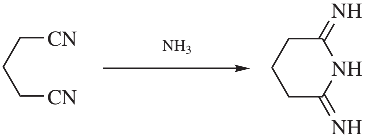
16-21 The Addition of Ammonia or Amines to Nitriles

N-Hydro-*C*-amino-addition



Unsubstituted amidines (in the form of their salts) can be prepared by addition of ammonia to nitriles.[425] Many amidines have been made in this way. Dinitriles of suitable chain length can give imidines:[426]



Primary and secondary amines can be used instead of ammonia, to give substituted amidines, but only if the nitrile contains electron-withdrawing groups; for example, Cl_3CCN gives the reaction. Ordinary nitriles do not react, and, in fact, acetonitrile is often used as a solvent in this reaction.[427] Ordinary nitriles can be converted to amidines by treatment with an alkylchloroaluminum amide, $MeAl(Cl)NR_2$ (R = H or Me).[428] The addition of ammonia to cyanamide (NH_2CN) gives guanidine, $(NH_2)_2C{=}NH$. Guanidines can also be formed from amines.[429]

If water is present, in the presence of a ruthenium catalyst[430] or a platinum catalyst,[431] the addition of a primary or secondary amine to a nitrile gives an amide: $RCN + R^1NHR^2 + H_2O \rightarrow RCONR^1R^2 + NH_3$ (R^2 may be H). When benzonitrile reacts with $H_2PO_3Se^-$ in aqueous methanol, a selenoamide, PhC=Se)NH_2, is formed after treatment with aq. potassium carbonate.[432]

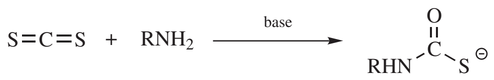
16-22 The Addition of Amines to Carbon Disulfide and Carbon Dioxide

***S*-Metallo-*C*-alkylamino-addition**



Salts of dithiocarbamic acid can be prepared by the addition of primary or secondary amines to carbon disulfide.[433] This reaction is similar to **16-10**. Hydrogen sulfide can be eliminated from the product, directly or indirectly, to give isothiocyanates (RNCS). Isothiocyanates can be obtained directly by the reaction of primary amines and CS_2 in pyridine in the presence of dicyclohexylcarbodiimide.[434] Aniline derivatives react with CS_2 and NaOH, and then ethyl chloroformate to give the aryl isothiocyanate.[435] In the presence of diphenyl phosphite and pyridine, primary amines add to CO_2 and to CS_2 to give, respectively, symmetrically substituted ureas and thioureas:[436] Isoselenoureas, $R_2NC(=NR^1)SeR^2$, can also be formed.[437]

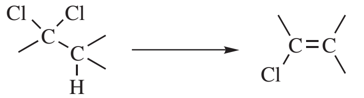
E. Halogen Nucleophiles

16-23 The Formation of *gem*-Dihalides from Aldehydes and Ketones

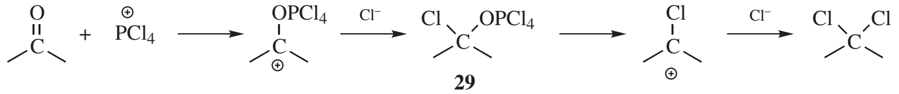
Dihalo-de-oxo-bisubstitution

Aliphatic aldehydes and ketones can be converted to *gem*-dichlorides[438] by treatment with PCl_5. The reaction fails for perhalo ketones.[439] If the aldehyde or ketone has an α hydrogen, elimination of HCl may follow and a vinylic chloride is a frequent side product:[440]



or even the main product.[441] The PBr_5 does not give good yields of *gem*-dibromides,[442] but these can be obtained from aldehydes, by the use of Br_2 and triphenyl phosphite.[443] *gem*-Dichlorides can be prepared by reacting an aldehyde with $BiCl_3$.[444]

The mechanism of *gem*-dichloride formation involves initial attack on PCl_4^+ (which is present in solid PCl_5) at the oxygen, followed by addition of Cl^- to the carbon:[445]



This chloride ion may come from PCl_6^- (which is also present in solid PCl_5). There follows a two-step S_N1 process. Alternatively, **29** can be converted to the product without going through the chlorocarbocation, by an S_Ni process.

This reaction has sometimes been performed on carboxylic esters, though these compounds very seldom undergo any addition to the C=O bond. An example is the conversion of $F_3CCOOPh$ to F_3CCCl_2OPh.[446] However, formates commonly give the reaction.

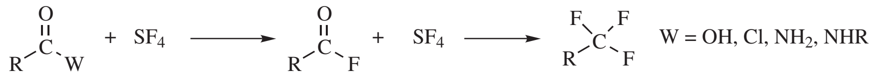
Many aldehydes and ketones have been converted to *gem*-difluoro compounds with sulfur tetrafluoride SF_4,[447] including quinones, which give 1,1,4,4-tetrafluorocyclohexadiene derivatives. With ketones, yields can be raised and the reaction temperature lowered, by the addition of anhydrous HF.[448] Carboxylic acids, acyl chlorides, and amides react with SF_4 to give 1,1,1-trifluorides. In these cases the first product is the acyl fluoride, which then undergoes the *gem*-difluorination reaction:



The acyl fluoride can be isolated. Carboxylic esters also give trifluorides, but more vigorous conditions are required. In this case, the carbonyl group of the ester is attacked first, and RCF_2OR' can be isolated from RCOOR′[449] and then converted to the trifluoride. Anhydrides can react in either manner. Both types of intermediate are isolable under the right conditions and SF_4 even converts carbon dioxide to CF_4. A disadvantage of reactions with SF_4 is that they require a pressure vessel lined with stainless steel. Selenium tetrafluoride SeF_4 gives similar reactions, but atmospheric pressure and ordinary glassware can be used.[450] Another reagent that is often used to convert aldehydes and ketones to *gem*-difluorides is the commercially available diethylaminosulfur trifluoride (DAST, Et_2NSF_3), and CF_2Br_2 in the presence of zinc.[451] The mechanism with SF_4 is probably similar in general nature, if not in specific detail, to that with PCl_5.

Treatment with hydrazine to give the hydrazone, and then $CuBr_2$/*t*-BuOLi, generated the *gem*-dibromide.[452] Oximes gives *gem*-dichlorides upon treatment with chlorine and BF_3•OEt_2, and then HCl.[453] Some dithianes can be converted to *gem*-difluorides with a mixture of fluorine and iodine in acetonitrile.[454] Oximes give *gem*-difluorides with $NO^+BF_4^-$ and pyridinium polyhydrogen fluoride.[455]

In a related process, α-halo ethers can be prepared by treatment of aldehydes and ketones with an alcohol and HX. The reaction is applicable to aliphatic aldehydes and ketones and to primary and secondary alcohols. The addition of HX to an aldehyde or ketone gives α-halo alcohols, which are usually unstable, although exceptions are known, especially with perfluoro and perchloro species.[456]

Aromatic aldehydes are converted to benzylic bromides with dibromoboranes, such as c-$C_6H_{11}BBr_2$.[457] Aldehydes are converted directly to benzylic chlorides with $HSiMe_2Cl$ and an $In(OH)_3$ catalyst.[458] The reaction of $BuBCl_2$ and oxygen gives alkylation (**16-25**) and chlorination.[459]

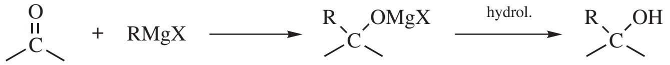
F. Attack at Carbon by Organometallic Compounds[460]

16-24 The Addition of Grignard Reagents and Organolithium Reagents to Aldehydes and Ketones

O-Hydro-*C*-alkyl-addition



Organomagnesium compounds, commonly known as Grignard reagents (RMgX), are formed by the reaction of alkyl, vinyl, or aryl halides with magnesium metal, usually in ether solvents such as diethyl ether or THF (**12-38**), although the reaction can be done in water[461] under certain conditions. Halogen–magnesium exchange generates a Grignard reagent by reaction of aryl halides with reactive aliphatic Grignard reagents.[462] The addition of Grignard reagents to aldehydes and ketones [463] is known as the *Grignard reaction.*[464] The initial product is a magnesium alkoxide, requiring a hydrolysis step to generate the final alcohol product. Formaldehyde gives primary alcohols; other aldehydes give secondary alcohols; and ketones give tertiary alcohols. The reaction is of very broad scope. In many cases, the hydrolysis step is carried out with dilute HCl or H_2SO_4, but this cannot be done for tertiary alcohols in which at least one R group is alkyl because such alcohols are easily dehydrated under acidic conditions (**17-1**). In such cases (and often for other alcohols as well), an aqueous solution of ammonium chloride is used instead of a strong acid. Grignard reagents have been used in solid phase synthesis.[465]

Alternative methods to generate the arylmagnesium compound are available, including the reaction of an aryl bromide with Bu_3MgLi in THF.[466] Subsequent addition of an aldehyde leads to addition of the aryl group to form an alcohol. An interesting method to form an alkylmagnesium halide used dibutylmagnesium (Bu_2Mg) and a chiral diamine, and subsequent reaction with an aldehyde led to the alcohol derived from acyl addition of a butyl group with good enantioselectivity.[467]

Organolithium reagents (RLi), prepared from alkyl halides and lithium metal or by exchange of an alkyl halide with a reactive organolithium (**12-38**) react with aldehydes and ketones by acyl addition to give the alcohol,[468] after hydrolysis. Organolithium reagents are more basic than the corresponding Grignard reagent, which leads to problems of deprotonation in some cases. Organolithium regents are generally more nucleophilic, and can add to hindered ketones with relative ease when compared to the analogous Grignard reagent.[469] These reagents tend to form aggregates, which influences the reactivity and selectivity of the addition reaction.[470] Alkyl, vinyl[471] and aryl organolithium reagents can be prepared and undergo this reaction. Structural variations are also possible. A lithio-epoxide was formed by treating an epoxide with *sec*-butyllithium in the presence of sparteine,[472] or with *n*-butyllithium/TMEDA,[473] and subsequent reaction with an aldehyde led to an epoxy alcohol. Treatment of an allenic silyl enol ether ($R_3SiOC{=}C{=}C$) with *tert*-butyllithium and then a ketone leads to acyl addition of a vinyllithium reagents to give a product with a conjugated ketone in which the C=C is allylic to the alcohol, $R_3SiC({=}O)C({=}CH_2){-}C(OH)R_2$.[474] The dilithio compound $LiC{\equiv}CCH_2Li$ reacts with ketones via acyl addition, and an interesting workup with formaldehyde and then aqueous ammonium chloride gave the homopropargyl alcohol, $R_2C(OH)CH_2C{\equiv}CH$.[475] Aryl sulfonamides can be treated with 2 equivalents of *n*-butyllithium to give an ortho aryllithium which can then be added to an aldehyde to give the resulting diaryl carbinol.[476] A very interesting variation of the fundamental acyl addition reaction of organolithium reagents treated an aldehyde with an acyllithio amide, $LiC({=}O)N(Me)CH_2Me$, to give an α-hydroxy amide derivative.[477]

The reaction of aldehydes or ketones with alkyl and aryl Grignard reagents has also been done without preliminary formation of RMgX, by mixing RX the carbonyl compound and magnesium metal in an ether solvent. This approach

preceded Grignard's work, and is now known as the *Barbier reaction*.[478] The organolithium analog of this process is also known.[479] Yields were generally satisfactory. Carboxylic ester, nitrile, and imide groups in the R are not affected by the reaction conditions.[480] Modern versions of the Barbier reaction employ other metals and/or reaction conditions, and will be discussed in **16-25**. A retro-Barbier reaction has been reported in which a cyclic tertiary alcohol was treated to an excess of bromine and potassium carbonate to give 6-bromo-2-hexanone from 1-methylcyclopentanol.[481] This section will focus on variations of the Barbier reaction that employ Mg or Li derivatives. The reaction of allyl iodide, benzaldehyde and Mg/I_2, for example, gave the acyl addition product 1-phenylbut-3-en-1-ol.[482]

The reaction of RMgX or RLi with α,β-unsaturated aldehydes or ketones can proceed via 1,4-addition as well as normal 1,2-addition (see **15-25**).[483] In general, alkyllithium reagents give less 1,4-addition than the corresponding Grignard reagents.[484] Quinones add Grignard reagents on one or both sides or give 1,4-addition. In a compound containing both an aldehyde and a ketone it is possible to add RMgX chemoselectively to the aldehyde without significantly disturbing the carbonyl of the ketone group[485] (see also, p. 1306). In conjunction with $BeCl_2$, organolithium reagents add to conjugated ketones. In THF, 1,4- addition is observed, but in diethyl ether the 1,2-addition product is formed.[486] Organocerium reagents, generated from cerium chloride ($CeCl_3$ and a Grignard reagent or an organolithium reagent) gives an organometallic reagent that adds chemoselectively.[487] Grignard reagents with a catalytic amount of $InCl_3$ to give a mixture of 1,2- and 1,4-addition products with the 1,4-product predominating, but there was an increased 1,2-addition relative to the uncatalyzed reaction.[488]

As with the reduction of aldehydes and ketones (**19-36**), the addition of organometallic compounds to these substrates can be carried out enantioselectively and diastereoselectively.[489] Chiral secondary alcohols have been obtained with high

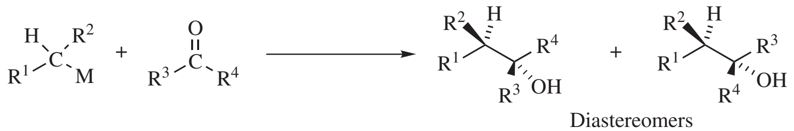
enantioselectivity by addition of Grignard and organolithium compounds to aromatic aldehydes, in the presence of optically active amino alcohols as ligands.[490]

Diastereoselective addition[491] has been carried out with achiral reagents and chiral substrates,[492] similar to the reduction shown on p. 1802.[493] Because the attacking atom in this case is carbon, not hydrogen, it is also possible to get diastereoselective addition with an achiral substrate and an optically active reagent.[494] Use of suitable reactants creates, in the most general case, two new stereogenic centers, so the product can exist as two pairs of enantiomers:



Even if the organometallic compound is racemic, it still may be possible to get a diastereoselective reaction; that is, one pair of enantiomers is formed in greater amount than the other.[495]

In some cases, the Grignard reaction can be performed intramolecularly.[496] For example, treatment of 5-bromo-2-pentanone with magnesium and a small amount

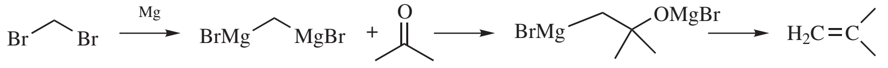
of mercuric chloride in THF produced 1-methyl-1-cyclobutanol in 60% yield.[497] Other four- and five-membered ring compounds were also prepared by this procedure. Similar closing of five- and six-membered rings was achieved by treatment of a δ- or ε-halocarbonyl compound, not with a metal, but with a dianion derived from nickel tetraphenyporphine.[498]



The *gem*-disubstituted magnesium compounds formed from CH_2Br_2 or CH_2I_2 (**12-38**) react with aldehydes or ketones to give alkenes in moderate-to-good yields.[499] Wittig type reacts also produce alkenes and are discussed in **16-44**. The reaction could not be extended to other *gem*-dihalides. Similar reactions with *gem*-dimetallic compounds prepared with metals other than magnesium have also produced alkenes.[500] An interesting variation is the reaction of methyllithium and CH_2I_2 with an aliphatic aldehyde to give an epoxide,[501] but this reagent reacted with lactones to give a cyclic hemiketal with a pendant iodomethyl unit.[502] Alkylidene oxetanes react with lithium, and then with an aldehyde to give a conjugated ketone.[503] The α,α-dimetallic derivatives of phenyl sulfones ($PhSO_2CM_2R$) (M = Li or Mg) react with aldehydes or ketones $R'COR^2$ to give good yields of the α,β-unsaturated sulfones $PhSO_2CR{=}CR'R^2$,[504] which can be reduced with aluminum amalgam (see **10-67**) or with $LiAlH_4$-$CuCl_2$ to give the alkenes $CHR{=}CR'R^2$.[505] On the other hand, *gem*-dihalides treated with a carbonyl compound and Li or BuLi give epoxides[506] (see also, **16-46**).

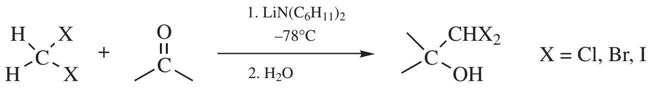
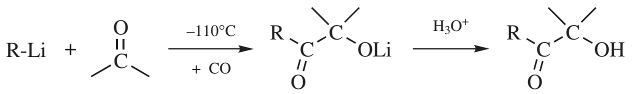
In other uses of *gem*-dihalo compounds, aldehydes and ketones add the CH_2I group [$R_2CO \rightarrow R_2C(OH)CH_2I$] when treated with CH_2I_2 in the presence of SmI_2,[507] and the CHX_2 group when treated with methylene halides and lithium dicyclohexylamide at low temperatures.[508]



A hydroxymethyl group can be added to an aldehyde or ketone with the masked reagent $Me_2((i\text{Pr})O)SiCH_2MgCl$, which with R_2CO gives $R_2C(OH)CH_2$-$Si(O{-}(i\text{Pr}))Me_2$, but with H_2O_2 give 1,2-diols $R_2C(OH)CH_2OH$.[509]

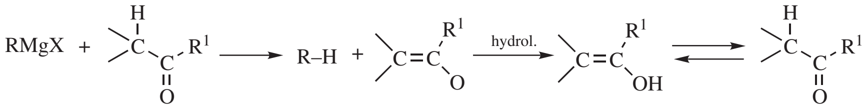
It is possible to add an acyl group to a ketone to give (after hydrolysis) an α-hydroxy ketone.[510] This can be done by adding RLi and CO to the ketone at −110°C:[511]



When the same reaction is carried out with carboxylic esters ($R'COOR^2$), α-diketones (RCOCOR′) are obtained.[511]

Most aldehydes and ketones react with most Grignard reagents, but there are several potential side reactions[512] that occur mostly with hindered ketones and with bulky Grignard reagents. The two most important of these are *enolization* and *reduction*. The former requires that the aldehyde or ketone have an α hydrogen, and the latter requires that the Grignard reagent have a β hydrogen:

Enolization



Reduction

Enolization is an acid–base reaction (**12-24**) in which a proton is transferred from the α carbon to the Grignard reagent. The carbonyl compound is converted to its enolate anion form, which, on hydrolysis, gives the original ketone or aldehyde. Enolization is important not only for hindered ketones but also for those that have a relatively high percentage of enol form (e.g., β-keto esters). In reduction, the carbonyl compound is reduced to an alcohol (**16-24**) by the Grignard reagent, which itself undergoes elimination to give an alkene. Two other side reactions are condensation (between enolate ion and excess ketone) and Wurtz-type coupling (**10-64**). Such highly hindered tertiary alcohols as triisopropylcarbinol, tri-*tert*-butylcarbinol, and diisopropylneopentylcarbinol cannot be prepared (or can be prepared only in extremely low yields) by the addition of Grignard reagents to ketones, because reduction and/or enolization become prominent.[513] However, these carbinols can be prepared by the use of alkyllithium reagents at $-80°C$[514] because enolization and reduction are much less important.[515] Other methods of increasing the degree of addition at the expense of reduction include complexing the Grignard reagent with $LiClO_4$ or Bu_4N^+ Br^-,[516] or using benzene or toluene instead of ether as solvent.[517] Both reduction and enolization can be avoided by adding $CeCl_3$ to the Grignard reagent (see above).[518]

Another way to avoid complications is to add $(RO)_3TiCl$, $TiCl_4$,[519] $(RO)_3ZrCl$, or $(R_2N)_3TiX$ to the Grignard or lithium reagent. This produces organotitanium or organozirconium compounds that are much more selective than Grignard or organolithium reagents.[520] An important advantage of these reagents is that they do not react with NO_2 or CN functions that may be present in the substrate, as Grignard and organolithium reagents do. The reaction of a β-keto amide with $TiCl_4$, for example, gives a complex that allows selective reaction of the ketone unit with MeMgCl—$CeCl_3$ to give the corresponding alcohol.[521] Premixing an allylic Grignard reagent with $ScCl_3$ prior to reaction with the aldehyde gives direct acyl addition without allylic rearrangement as the major product, favoring the trans-alkene unit.[522]

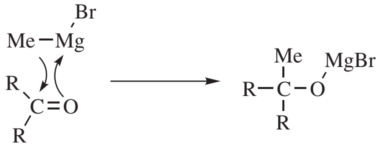
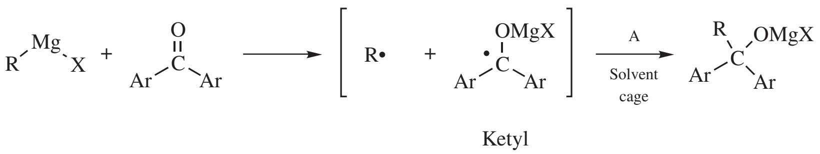
There has been much controversy regarding the mechanism of addition of Grignard reagents to aldehydes and ketones.[523] The reaction is difficult to study because of the variable nature of the species present in the Grignard solution (p. 260) and because the presence of small amounts of impurities in the magnesium seems to have a great effect on the kinetics of the reaction, making reproducible experiments difficult.[524] There seem to be two basic mechanisms, depending on the reactants and the reaction conditions. In one of these, the R group is transferred to the carbonyl carbon with its electron pair. A detailed mechanism of this type has been proposed by Ashby and co-workers,[525] based on the discovery that this reaction proceeds by two paths: one first order in MeMgBr and the other first order in Me_2Mg.[526] According to this proposal, both MeMgBr and Me_2Mg add to the carbonyl carbon, though the exact nature of the step by which MeMgBr or Me_2Mg reacts with the substrate is not certain. One possibility is a four-centered cyclic transition state:[527]



The other type of mechanism is a single electron transfer (SET) process[528] with a ketyl intermediate:[529]



This mechanism, which has been mostly studied with diaryl ketones, is more likely for aromatic and other conjugated aldehydes and ketones than it is for

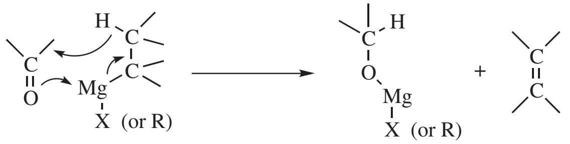
strictly aliphatic ones. Among the evidence[530] for the SET mechanism are ESR spectra[531] and the fact that

side products are obtained (from dimerization of the ketyl).[532] In the case of addition of RMgX to benzil (PhCOCOPh), esr spectra of two different ketyl radicals were observed, both reported to be quite stable at room temperature.[533] Note that a separate study failed to observe freely defusing radicals in the formation of Grignard reagents.[534] Carbon isotope effect studies with $Ph^{14}COPh$ showed that the rate-determining step with most Grignard reagents is the carbon–carbon bond-forming step (marked *A*), though with allylmagnesium bromide it is the initial electron-transfer step.[535] In the formation of Grignard reagents from bromocyclopropane, diffusing cyclopropyl radical intermediates were found.[536] The concerted versus stepwise mechanism has been probed with chiral Grignard reagents.[537]

Mechanisms for the addition of organolithium reagents have been investigated much less.[538] Addition of a cryptand that binds Li^+ inhibited the normal addition reaction, showing that the lithium is necessary for the reaction to take place.[539]

There is general agreement that the mechanism leading to reduction[540] is usually as follows:



Reduction

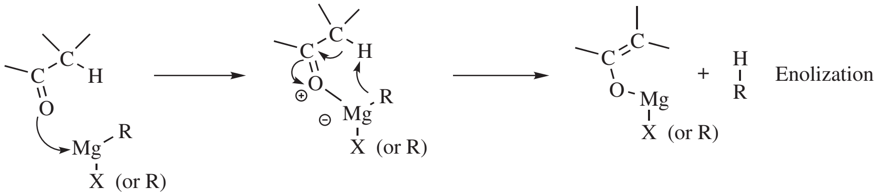
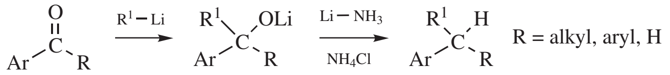
There is evidence that the mechanism leading to enolization is also cyclic, but involves prior coordination with magnesium:[541]



Aromatic aldehydes and ketones can be alkylated and reduced in one reaction vessel by treatment with an alkyl- or aryllithium, followed by lithium and ammonia and then by ammonium chloride.[542]



A similar reaction has been carried out with *N,N*-disubstituted amides: $RCONR'_2 \rightarrow RR^2CHNR'_2$.[543]

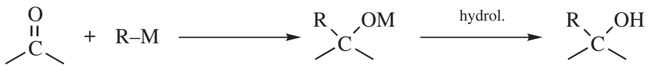
16-25 Addition of Other Organometallics to Aldehydes and Ketones

***O*-Hydro-*C*-alkyl-addition**



A variety of organometallic reagents other than RMgX and RLi add to aldehydes and ketones. A simple example is formation of sodium, or potassium alkyne anions (e.g., RC≡CNa, **16-38**), which undergo acyl addition to ketones or aldehydes to give the propargylic alcohol. For the addition of acetylenic groups, sodium may be the metal used; while vinylic alanes (prepared as in **15-17**) are the reagents of choice for the addition of vinylic groups.[544] A variation includes the use of tetraalkylammonium hydroxide to generate the alkyne anion,[545] and terminal alkynes with CsOH react similarly.[546] A solvent-free reaction was reported that mixed a ketone, a terminal alkyne and potassium *tert*-butoxide.[547] The reagent $Me_3Al/^{-}C{\equiv}CH$

Na^+ also adds to aldehydes to give the ethynyl alcohol.[548] Dialkylzinc reagents have been used for the same purpose, and in the presence of a chiral titanium complex the propargylic alcohol was formed with good enantioselectivity.[549] Zinc(II) chloride facilitates the addition of a terminal alkyne to an aldehyde to give a propargylic alcohol.[550] Zinc(II) triflate can also be used for alkyne addition to aldehydes,[551] and in the presence of a chiral ligand leads to good enantioselectivity in the propargyl alcohol product.[552] Terminal alkynes add to aryl aldehydes in the presence of $InBr_3$ and NEt_3[553] or SmI_2.[554] 1-Iodoalkynes react with In metal and an aldehyde to give the propargylic alcohol.[555] Potassium alkynyltrifluoroborates (p. 817) react with aldehydes and a secondary amine, in an ionic liquid, to give a propargylic amine.[556]

Propargylic acetate adds to aldehydes with good anti selectivity in the presence of Et_2Zn and a palladium catalyst.[557] Propargylic bromide add to ketones in the presence of NaI/Dy,[558] In,[559] or Mn/Cr catalyst/TMSCl.[560] Propargylic tin compounds react with aldehydes to give the alcohol, with good antiselectivity.[561]

With other organometallic compounds, active metals, such as alkylzinc reagents,[562] are useful; and compounds such as alkylmercurys do not react. When the reagent is $MeNbCl_4$, ketones (R_2CO) are converted to $R_2C(Cl)Me$.[563]

Furthermore, organotitanium reagents can be made to add chemoselectively to aldehydes in the presence of ketones.[564] Organomanganese compounds are also chemoselective in this way.[565] Aryl halides that have a pendant ketone unit react with a palladium catalyst to give cyclization via acyl addition.[566] Chiral amides react with aldehydes in the presence of $TiCl_4$ to give syn-selective addition products,[567] and titanium-catalyzed enantioselective additions are known.[568] An alkene-ketone, where the alkene is a vinyl bromide, reacted with $CrCl_2/NiCl_2$ to give a vinyl organometallic, which cyclized to generate a cyclic allylic alcohol with the double bond within the ring.[569] Aryl halides react with a nickel complex under electrolytic conditions to add the aryl group to aldehydes.[570] The C-3 position of an indole adds to aldehydes in the presence of a palladium catalyst.[571] The addition of trifluoromethyl to an aldehyde was accomplished photochemically using CF_3I and $(Me_2N)_2C{=}C(NMe_2)_2$.[572] α-Iodo phosphonate esters react with aldehydes and SmI_2 to give a β-hydroxy phosphonate ester.[573]

Dialkylzinc compounds react with aldehydes to give the secondary alcohol, and R_3ZnLi reagents also add R to a carbonyl.[574] Dimethylzinc and diethylzinc are probably the most common reagents. An intramolecular version is possible by reaction an allene-aldehyde with dimethylzinc. Addition to the allene in the presence of a nickel catalyst[575] or a $CeCl_3$ catalyst[576] is followed by addition of the intermediate organometallic to the aldehyde to give the cyclic product. Aryl halides react with Zn–Ni complexes to give acyl addition of the aryl group to an aldehyde.[577] The reaction of an allylic halide and Zn[578] or Zn/TMSCl[579] leads to acyl addition of aldehydes.

Lithium dimethylcopper (Me_2CuLi) reacts with aldehydes[580] and with certain ketones[581] to give the expected alcohols. The RCu(CN)ZnI reagents also react with aldehydes, in the presence of BF_3–etherate, to give secondary alcohols. Vinyltellurium compound react with BF_3•OEt_2 and cyano cuprates [R(2-thienyl)CuCN-Li_2] to give a reagent that adds 1,2- to the carbonyl of a conjugated ketone.[582] Vinyl tellurium compounds also react with *n*-butyllithium to give a reagent that adds to nonconjugated ketones.[583]

Many methods have been reported for the addition of allylic groups,[584] including enantioselective reactions.[585] One of the most common methods is the Barbier reaction, employing metals and metal compounds other than Mg or Li, although the method is not limited to allylic compounds. Allyl indium compounds[586] add to aldehydes or ketones in various solvents.[587] Indium metal is used for the acyl addition of allylic halides with a variety of aldehydes and ketones, including aliphatic aldehydes,[588] aryl aldehydes[589] and α-keto esters.[590] Indium reacts with allylic bromides and ketones in water[591] and in aqueous media. Elimination of the homoallylic alcohol to a conjugated diene can accompany the addition in some cases.[592] The reaction of a propargyl halide, In, and an aldehyde in aq. THF leads to an allenic alcohol.[593] The reaction of benzaldehyde with a propargylic bromide, indium metal and water give the alcohol.[594] Allyl bromide reacts with Mn/TMSCl and an In catalyst in water to give the homoallylic

alcohols from aldehydes.[595] When allyl iodide is mixed with In and TMSCl, reaction with a conjugated ketone proceed by 1,4-addition, but in the presence of 10% CuI, the major product is that of 1,2-addition.[596] The reaction with indium is compatible with the presence of a variety of other functional groups in the molecule, including phosphonate,[597] propargylic sulfides.[598] Ethyl α-bromoacetate reacts with aldehydes using In with ultrasound.[599] Vinyl epoxides can be added to aldehydes using InI and a palladium catalyst,[600] and vinyl acetates react with indium metal to give a reactive intermediate that adds to the carbonyl of aldehydes.[601] A tandem reaction has been reported in which a bis(indium) reagent, $Br_2InC(=CH_2)–C(=CH_2)InBr_2$, reacts with 2 equivalents of an aldehyde in the presence of ZnF_2 to give a 3-hexyne-1,6-diol derivative.[602] Alkyl halides react with Zn/Cu and an InCl catalyst, in the presence of 0.07 *M* $Na_2Cr_2O_7$ to give an intermediate that adds to aldehydes.[603] Analogous to aldehydes, 1,1-diacetates react with In and allyl bromide in aq. THF to give a homoallylic acetate,[604] as do dimethyl ketals.[605] Allylic alcohols react with InI and a nickel catalyst to give acyl addition of an allylic group to an aldehyde, giving the homoallylic alcohol.[606]

Another important metal for Barbier-type reaction is samarium. Allyl bromide reacts with a ketone and Sm to give the homoallylic alcohol.[607] Samarium compounds, such as SmI_2,[608] can also be used with allylic halides.

Allyltin compounds readily add to aldehydes and ketones.[609] Allylic bromides react with tin to generate the organometallic *in situ*, which then adds to aldehydes.[610] Allylic chlorides react with aldehydes in the presence of ditin compounds such as $Me_3Sn–SnMe_3$ and a palladium catalyst.[611] Allyltrialkyltin compounds[612]

give the dienyl alcohol.[636] Allenyl tin compounds ($CH_2{=}C{=}CHSnBu_3$) also react with aldehydes in the presence of $BF_3{\bullet}OEt_2$ to give a 2-dienyl alcohol.[637] The tin compound can be prepared *in situ* using an α-iodo ketone with an aldehyde and Bu_2SnI_2—LiI.[638] A similar addition occurs with $(allyl)_2SnBr_2$ in water.[639] Asymmetric induction has been reported.[640] The use of a chiral rhodium[641] or titanium[642] catalyst leads to enantioselective addition of allyltributyltin to aldehydes. Allyltributyltin reacts with aldehydes in the presence of $SiCl_4$ and a chiral phosphoramide to give the homoallylic alcohol with moderate enantioselectivity.[643] It is noted that tetraallyl germanium adds to aldehydes in a similar manner in the presence of a $Sc(OTf)_3$ catalyst.[644]

A variety of other allylic metal compounds add to aldehydes or ketones.[645] A variety of alkyl and allylic halides add to aldehydes or ketones in the presence of metals or metal compounds; the metal or compounds based on Ti,[646] Mn,[647] Fe,[648] Ga,[649]

Ge,[650] Zr,[651] Nb,[652] Cd,[653] Sn,[654] Sb,[655] Te,[656] Ba,[657] Ce,[658] Nd,[659] Hg,[660] Bi,[661] and Pb.[662] In addition, $BiCl_3/NaBH_4$,[663] Mg—$BiCl_3$,[664] and $CrCl_2/NiCl_2$,[665] have been used. Allylic alcohols have been converted to organometallic reagents with diethyl zinc and a palladium catalyst[666] or a ruthenium catalyst[667] leading to the homoallylic alcohol upon reaction with an aldehyde. A chiral Cr/Mn complex has been used with allylic bromides in conjunction with trimethylsilyl chloride.[668] Reagents of the type R—Yb have been prepared from RMgX.[669] Vinyl bromides react with $NiBr_2/CrCl_3$/TMSCl to give a reagent that adds to aldehydes to give the allylic alcohol.[670] Vinyl complexes generated from alkynes and SmI_2 add intramolecularly, and eight-membered rings have been formed in this way.[671] Allylic alcohols add to aldehydes in some cases, using $SnCl_2$ and a palladium catalyst.[672] Glyoxal reacted with 2 equivalents of allyl bromide and $SnCl_2$ with KI in water, to give the bis-homoallylic alcohol oct-1,7-diene-4,5-diol.[673] The alkyl group of trialkyl aluminum compounds such as $AlEt_3$ add to aldehydes, enantioselectively in the presence of chiral transition-metal complexes.[674] Certain functional groups (COOEt, $CONMe_2$, CN) can be present in the R group when

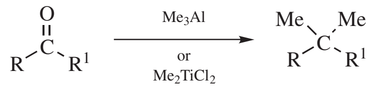
organotin reagents $RSnEt_3$ are added to aldehydes.[675] Trimethylaluminum[676] and dimethyltitanium dichloride[677] exhaustively methylate ketones to give *gem*-dimethyl compounds[678] (see also **10-63**):



The titanium reagent also dimethylates aromatic aldehydes.[679] Triethylaluminum reacts with aldehydes, however, to give the mono-ethyl alcohol, and in the presence of a chiral additive the reaction proceeds with good asymmetric induction.[680] A complex of Me_3Ti•MeLi has been shown to be selective for 1,2-addition with conjugated ketones, in the presence of nonconjugated ketones.[681] In other variations, the organometallic reagent is generated *in situ*. 1,4-Dimethoxybenzene reacts with ethyl glyoxylate (EtO_2C—CHO) in the presence of 5% $Yb(OTf)_3$, to give the alcohol formed by addition of the aryl group to the aldehyde unit.[682]

High ee values have also been obtained with organometallics,[683] including organotitanium compounds (methyl, aryl, allylic) in which an optically active ligand is coordinated to the titanium,[684] allylic boron compounds, and organozinc compounds. As for the organozinc reagents, very high enantioselection was obtained from R_2Zn reagents (R = alkyl)[685] and aromatic[686] aldehydes by the use of a small

amount of various catalysts.[687] The enantioselectivity is influenced by additives, such as LiCl.[688] Silica-immobilized chiral ligands[689] can be used in conjunction with dialkylzinc reagents, and polymer-supported ligands have been used.[690]. Chiral dendritic titanium catalysts have been used to give moderate enantioselectivity.[691]

Enantioselective reaction of a carbonyl with a dialkylzinc is possible when other functional groups are present in the molecule. Examples include keto esters.[692] An enzyme-mediated addition of dialkylzinc reagents to aldehydes has also been reported.[693] When benzaldehyde was treated with Et_2Zn in the presence of the optically active catalyst 1-piperidino-3,3-dimethyl-2-butanol, a surprising result was obtained. Although the catalyst had only 10.7% excess of one enantiomer, the

product PhCH(OH)Me had an ee of 82%.[694] When the catalyst ee was increased to 20.5%, the product ee rose to 88%. The question is, how could a catalyst produce a product with an ee much higher than itself? One possible explanation[695] is that (*R*) and (*S*) molecules of the catalyst form a complex with each other, and that only the uncomplexed molecules are actually involved in the reaction. Since initially the number of (*R*) and (*S*) molecules was not the same, the (*R/S*) ratio of the uncomplexed molecules must be considerably higher (or lower) than that of the initial mixture.

Although organoboranes do not generally add to aldehydes and ketones,[696] allylic boranes are exceptions.[697] When they add, an allylic rearrangement always takes place. Allylic rearrangements take place with the other reagents as well. The use of a chiral catalyst leads to asymmetric induction[698] and chiral allylic boranes have been prepared.[699] It is noted that chloroboranes (R_2BCl) react with aldehydes via acyl addition of the alkyl group, giving the corresponding alcohol after treatment with water.[700] A variation is the reaction of a diketone, where one carbonyl is conjugated. Treatment with catecholborane gives addition to the conjugated ketone, and subsequent cyclization of the resulting organometallic at the nonconjugated ketone gives a cyclic alcohol with a pendant ketone unit, after treatment with methanol.[701] In the presence of ruthenium complexes, $RB(OH)_2$ and arylboronic acids $ArB(OH)_2$ (p. 815) add to aldehydes to give the corresponding alcohol.[702] Polymer-bound aryl borates add an aryl group to aldehydes in the presence of a rhodium catalyst.[703] An intramolecular version of the phenylboronic acid-induced reaction is known, where a molecule with ketone and conjugated ketone units is converted to a cyclic alcohol using a chiral rhodium catalyst.[704] Allylic boronates add to aldehydes.[705]

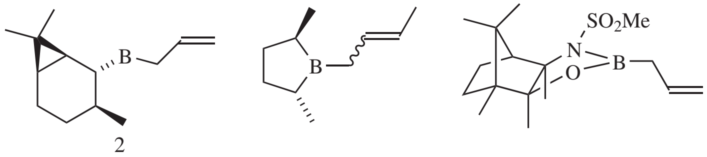
A number of optically active allylic boron compounds have been used, including[706] B-allylbis(2-isocaranyl)borane (**30**),[707] (*E*)- and (*Z*)-crotyl-(*R*,*R*)-2,5-dimethylborolanes (**31**),[708] and the borneol



30 **31** **32**

derivative **32**,[709] all of which add an allyl group to aldehydes, with good enantioselectivity. Where the substrate possesses an aryl group or a triple bond, enantioselectivity is enhanced by using a metal carbonyl complex of the substrate.[710]

Alkenes and alkynes add to aldehydes or ketones by conversion to a reactive organometallic. A radical-type addition is possible using alkenes with BEt_3. Benzaldehyde reacted with isoprene in the presence of BEt_3 and $Ni(acac)_2$ to give an anti-Markovnikov-type addition to the carbonyl, C=C—C(Me)=C + PhCHO → $C{=}CCHMeCH_2CH(OH)Ph$.[711] Alkynes add to aldehydes elsewhere in the same molecule in the presence of BEt_3 and a nickel catalyst to give a cyclic allylic alcohol.[712] Alkene aldehydes react similarly using Me_3SiOTf.[713] In a similar manner, dienes add to aldehydes in the presence of a nickel catalyst.[714] Propargylic halides add to aldehydes to give an allenic alcohol using β-SnO$[Rd(cod)Cl]_2$.[715] Allylic acetates react with ketones to give the homoallylic alcohol under electrochemical conditions that include bipyridyl, tetrabutylammonium tetrafluoroborate and $FeBr_2$.[716] Terminal alkynes react with zirconium complexes and Me_2Zn to give an allylic tertiary alcohol.[717] Internal alkynes also give allylic alcohols in the presence of BEt_3 and a nickel catalysts.[718] Reaction of an aldehyde containing a conjugated diene unit with diethylzinc and a nickel catalyst leads to cyclic

alcohols having a pendant allylic unit.[719] A similar reaction was reported using a copper catalyst.[720] Vinyl iodides also react with Cp_2ZrCl_2 to give a vinylzirconium complex that reacts with aldehydes.[721] The intramolecular addition of an alkene to an aldehyde leads to a saturated cyclic alcohol using $PhSiH_3$ and a cobalt catalyst.[722] Intramolecular addition of a conjugated ester (via the β-carbon) to an aldehyde generates a cyclic ketone.[723] This type of coupling has been called the *Stetter reaction*,[724] which actually involves the addition of aldehydes to activated double bonds (**15-34**), mediated by a catalytic amount of thiazolium salt in the presence of a weak base. The intramolecular addition of the allene moiety to an aldehyde is catalyzed by a palladium complex in the presence of $Me_3SiSnBu_3$.[725] A highly enantio- and diastereoselective intramolecular Stetter reaction has been developed.[726] Alkynyl aldehydes react with silanes such as Et_3SiH and a nickel catalyst to give a cyclic compound having a silyl ether and an exocyclic vinylidene unit.[727] Alkene-aldehydes give cyclic alcohols via intramolecular addition of the C=C unit to the carbonyl under electrolytic conditions using a phase-transfer catalyst.[728] A similar cyclization was reported using $SnCl_4$.[729] Vinylidene cycloalkanes react with aldehydes in the presence of a palladium catalyst to give a homoallylic alcohol where addition occurs at the carbon exocyclic to the ring.[730] Alkenes having an allylic hydrogen react with α-keto aldehydes, with a cobalt catalyst, to give α-hydroxy ketones where the alcohol is homoallylic relative to the C=C unit.[731] Allenes react with benzaldehyde using HCl—$SnCl_2$ with a palladium catalyst.[732] Silyl allenes react with aldehydes in the presence of a chiral scandium catalyst to give homopropargylic alcohols with good enantioselectivity.[733] Intramolecular addition of an allene to aldehyde via addition of phenyl when treated with PhI and a palladium catalyst.[734] Allenes add to ketones

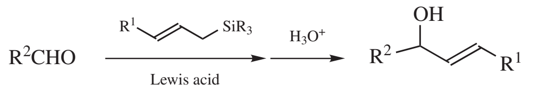
to give homoallylic alcohols in the presence of SmI_2 and HMPA.[735] Allenes add to carbonyl groups in the presence of 2.2 equivalents of SmI_2 and an excess of HMPA.[736] Alkenes have an allylic methyl group add to formaldehyde, in the presence of BF_3•OEt_2, to give a homoallylic alcohol.[737] Conjugated dienes react with aldehyde via acyl addition of a terminal carbon of the diene, in the presence of $Ni(acac)_2$ and Et_2Zn.[738] Aldehydes having an allylic acetate unit elsewhere in the molecule undergo cyclization in CO and a ruthenium catalyst to give a cyclic alcohol with a pendant vinyl group.[739]

Allylic trifluoroborates (p. 817) react with aldehydes to give the homoallylic alcohol. Pivaldehyde reacts with potassium 2-butenyltrifluoroborate and a catalytic amount of tetrabutylammonium iodide to give 2,2,4-trimethylhex-5-en-3-ol.[740] Aliphatic aldehydes react with this reagent, in the presence of BF_3•OEt_2, to give the homoallylic alcohol with allylic rearrangement and a preference for the syn diastereomer,[741] and aryl aldehydes react as well.[742]

16-26 Addition of Trialkylallylsilanes to Aldehydes and Ketones

***O*-Hydro-*C*-alkyl-addition**



Allylic trialkyl, trialkoxy, and trihalosilanes add to aldehydes to give the homoallylic alcohols in the presence of a Lewis acid[743] (including $TaCl_5$[744] and $YbCl_3$[745]), Me_3SiOTf,[746] fluoride ion,[747] proazaphosphatranes,[748] or a catalytic amount of iodine.[749] The mechanism of this reaction has been examined.[750] A ruthenium catalyst has also been used in conjunction with an arylsilane and an aldehyde.[751]

The reaction of an allene aldehyde with Et_3SiH, CO and a rhodium catalyst leads to addition to the alkene followed by intramolecular addition to the aldehyde to give the cyclic alcohol.[752] Allyl(trimethoxy)silane adds an allyl group to aldehydes using a CdF_2[753] catalyst or a chiral AgF complex.[754] Allyltrichlorosilanes have also been used in addition reactions with aldehydes.[755] Hünig's base (*i*Pr_2NEt) and a sulfoxide have also been used to facilitate the addition of an allyl group to an aldehyde from allyltrichlorosilane.[756]

Allyltrichlorosilane reacts with benzaldehyde in the presence of Bu_4NF to give 1-phenylbut-3-en-1ol,[757] and with a chiral additive the reaction proceeds with good enantioselectivity. When chiral titanium complexes are used in the reaction, allylic alcohols are produced with good asymmetric induction.[758] Other chiral additives have been used,[759] as well as chiral catalysts,[760] and chiral complexes of allyl silanes.[761] Chiral allylic silyl derivatives add to aldehydes to give the chiral homoallylic alcohol.[762]

Allylic silanes react with *gem*-diacetates in the presence of $InCl_3$ to give a homoallylic acetate[763] or with dimethyl acetals and TMSOTf in an ionic liquid to give the homoallylic methyl ether.[764] Allylic alcohols can be treated with TMS—Cl and NaI, and then Bi to give an organometallic reagent that adds to aldehydes.[765]

16-27 Addition of Conjugated Alkenes to Aldehydes (the Baylis–Hillman Reaction)[766]

O-Hydro-*C*-alkenyl-addition

In the presence of a base,[767] such as 1,4-diazabicyclo[2.2.2]octane (DABCO) or trialkylphosphines, conjugated carbonyl compounds (ketones, esters,[768] thioesters,[769] and amides[770]) add to aldehydes via the α-carbon to give α-alkenyl-β-hydroxy esters or amides. This sequence is called the *Baylis–Hillman reaction*,[771] and a simple example is the formation of **33**.[772] It was observed that methyl vinyl ketone gave other products in the Baylis–Hillman reaction, whereas conjugated esters did not.[773] Methods that are catalytic in base have been developed for the Baylis–Hillman reaction.[774] Both microwave irradiation[775] and ultrasound[776] have been used to induce the reaction. Under certain conditions, rate enhancements have been observed.[777] Rate acceleration occurs with bis-aryl(thio)ureas in a DABCO-promoted reaction.[778] The reaction has been done in ionic liquids[779] and polyethylene glycol (PEG)[780] or sulpholane.[781] Alkynyl carbonyl compounds can be used as partners in the Baylis–Hillman reaction.[782] Transition metal compounds can facilitate the Baylis–Hillman reaction, and BF_3•OEt_2 has been used.[783] With the boron trifluoride

induced reaction between an aldehyde and a conjugated ketone, a saturated β-hydroxy ketone was formed with good antiselectivity.[784] The coupling of aldehydes with conjugated ketones was accomplished with $TiCl_4$,[785] dialkylaluminum halides,[786] and with (polymethyl)hydrosiloxane and a copper catalyst.[787] Conjugated esters were coupled to aldehydes with DABCO and a lanthanum catalyst.[788] Aldehydes were coupled to conjugated nitriles with $TiCl_4$.[789] The reaction of a conjugated ester, an aldehyde and $LiClO_4$, with 15% DABCO gave the allylic alcohol product.[790] *N*-Tosyl imines can be used in place of aldehydes, and the reaction of the imine, a conjugated ester and DABCO gave the allylic *N*-tosylimine.[791] Aldehydes are coupled to conjugated esters with a chiral quinuclidine catalyst and a titanium catalyst, and in the presence of tosylamine, the final product was the allylic *N*-tosylamine formed with modest enantioselectivity.[792]

An intramolecular version of the Baylis–Hillman reaction generated cyclopentenone derivatives from alkyne-aldehydes and a rhodium catalyst.[793] Another intramolecular reaction gave cyclopentenols via cyclization of an aldehyde-conjugated thioester upon treatment with DBU and DMAP.[794] Cyclization of a conjugated ester using DABCO, where the "alcohol" group contained an aldehyde unit (an α-hydroxy aldehyde derivative) gave a lactone with an hydroxy unit at C3 relative to the carbonyl and an α-vinylidene.[795] A "double Baylis–Hillman" reaction has also been reported using *N*-tosylimines and conjugated ketones.[796]

Using a chiral auxiliary via an amide[797] or ester[798] leads to asymmetric induction.[799] Aryl aldehydes and conjugated ketones were condensed using proline, leading to modest enantioselectivity.[800] Chiral biaryl catalysts have been used with trialkylphosphines, giving good enantioselectivity.[801] Chiral quinuclidine catalysts lead to

asymmetric induction.[802] A combination of a chiral sulfinamide, an In catalyst and 3-hydroxyquinuclidine led to the allylic amine derivative with modest enantioselectivity.[803] Sugars have been used as ester auxiliaries, and in reaction with aryl aldehydes and 20% DABCO gave the allylic alcohol with modest enantioselectivity.[804]

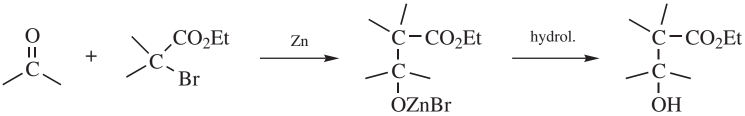
The reaction can be modified to give additional products, as with the reaction of *o*-hydroxybenzaldehyde and methyl vinyl ketone with DABCO, where the initial Baylis–Hillman product cyclized via conjugate addition of the phenolic oxygen to the conjugated ketone (**15-31**).[805] Aldehydes and conjugated esters can be coupled with a sulfonamide to give an allylic amine.[806]

A variant of this reaction couples halides with alkenes. α-Bromomethyl esters react with conjugated ketones and DABCO to give a coupling product, **34**.[807] A similar DBU-induced reaction was reported using α-bromomethyl esters and conjugated nitro compounds.[808]

34

16-28 The Reformatsky Reaction

O-Hydro-*C*-α-ethoxycarbonylalkyl-addition



The *Reformatsky reaction*[809] is very similar to **16-24**. An aldehyde or ketone is treated with zinc and a halide; the halide is usually an α-halo ester or a vinylog of an α-halo ester (e.g., RCHBrCH=CHCOOEt), though α-halo nitriles,[810] α-halo ketones,[811] and α-halo *N,N*-disubstituted amides have also been used. Especially

high reactivity can be achieved with activated zinc,[812] with zinc/silver-graphite,[813] and with zinc and ultrasound.[814] The reaction is catalytic in zinc in the presence of iodine and ultrasound.[815] Metals other than zinc can be used, including In,[816] Mn,[817] low valent Ti,[818] and metal compounds, such as TiI_4,[819] $TiCl_2$,[820] Cp_2TiCl_2,[821] $(Bu_3Sn)_2/Bu_2SnCl_2$,[822] SmI_2,[823] and $Sc(OTf)_3/PPh_3$.[824] A combination of Zn and an α-bromo ester can be used in conjunction with BF_3•OEt_2, followed by reaction with dibenzoyl peroxide.[825] The aldehyde or ketone can be aliphatic, aromatic, or heterocyclic or contain various functional groups. Solvents used are generally ethers, including Et_2O, THF, and 1,4-dioxane, although the reaction can be done in water[826] using dibenzoyl peroxide and $MgClO_4$.

Dialkylzinc compounds are an alternative source of zinc in the Reformatsky reaction. When an α-bromo ester, an aldehyde, and diethylzinc were reacted in THF with a rhodium catalyst, the β-hydroxy ester was formed.[827]

The use of additives, such as germanium, can lead to highly diastereoselective reactions.[828] Using chiral auxiliaries[829] or chiral additives,[830] good enantioselectivity[831] can be achieved.

Formally, the reaction can be regarded as if it were analogous to the Grignard reaction (**16-24**), with

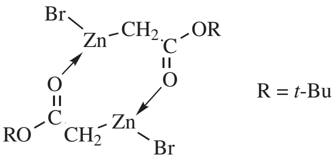
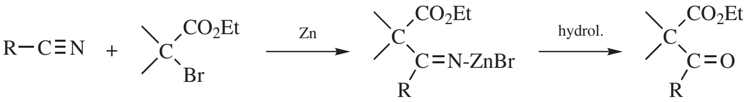
(**35**) as an intermediate analogous to RMgX.[832] There *is* an intermediate derived from zinc and the ester, the structure of which has been shown to be **36**, by X-ray crystallography of the solid intermediate prepared from *t*-$BuOCOCH_2Br$ and Zn.[833] As can be seen, it has some of the characteristics of **35**.

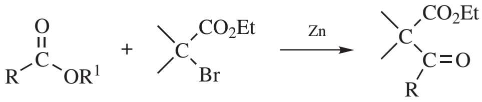


36

After hydrolysis, the alcohol is the usual product, but sometimes (especially with aryl aldehydes) elimination follows directly and the product is an alkene. By the use of Bu_3P along with Zn, the alkene can be made the main product,[834] making this an alternative to the Wittig reaction (**16-44**). The alkene is also the product when $K_2CO_3/NaHCO_3$ is used with 2% PEG–telluride.[835] Since Grignard reagents cannot be formed from α-halo esters, the method is quite useful, though there are competing reactions and yields are sometimes low. A similar reaction (called the *Blaise reaction*) has been carried out on nitriles:[836]



Carboxylic esters have also been used as substrates, but then, as might be expected (p. 1252), the result is substitution and not addition:



The product in this case is the same as with the corresponding nitrile, though the pathways are different. The reaction is compatible with amine substituents, and α-(*N,N*-dibenzyl)amino aldehydes have been used to prepare β-hydroxy-γ-(*N,N*-dibenzylamino) esters with good anti-selectivity.[837]

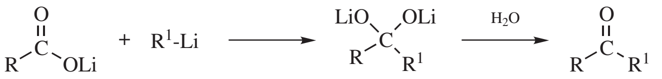
16-29 The Conversion of Carboxylic Acid Salts to Ketones with Organometallic Compounds

Alkyl-de-oxido-substitution



Good yields of ketones can often be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent, followed by hydrolysis.[838] The R′ group may be aryl or primary, secondary, or tertiary alkyl and R may be alkyl or aryl. The compounds MeLi and PhLi have been employed most often. Tertiary alcohols are side products. Lithium acetate can be used, but generally gives low yields.

A variation of this transformation reacts the acid with lithium naphthalenide in the presence of 1-chlorobutane. The product is the ketone.[839] A related reaction treats the lithium carboxylate with lithium metal and the alkyl halide, with sonication, to give the ketone.[840] Phenylboronic acid (p. 815) reacts with aryl carboxylic acids in the presence of a palladium catalyst and disuccinoyl carbonate to give a diaryl ketone.[841]

OS **V**, 775.

16-30 The Addition of Organometallic Compounds to CO_2 and CS_2

C-Alkyl-*O*-halomagnesio-addition

Grignard reagents add to one C=O bond of CO_2 exactly as they do to an aldehyde or a ketone.[842] Here, of course, the product is the salt of a carboxylic acid. The reaction is usually performed by adding the Grignard reagent to dry ice. Many carboxylic acids have been prepared in this manner, and this constitutes an important way of increasing a carbon chain by one unit. Since labeled CO_2 is commercially

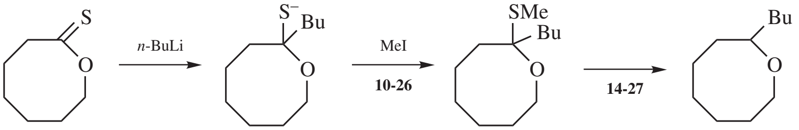
available, this is a good method for the preparation of carboxylic acids labeled in the carboxyl group. Other organometallic compounds have also been used (RLi,[843] RNa, RCaX, RBa,[844] etc.), but much less often. The formation of the salt of a carboxylic acid after the addition of CO_2 to a reaction mixture is regarded as a positive test for the presence of a carbanion or of a reactive organometallic intermediate in that reaction mixture (see also, **16-42**).

When chiral additives, such as (−)-sparteine, have added to the initial reaction with the organolithium reagent, quenching with CO_2 produces carboxylic acids with good asymmetric induction.[845]

In a closely related reaction, Grignard reagents add to CS_2 to give salts of dithiocarboxylic acids.[846] These salts can be trapped with amines to form thioamides.[847] Two other reactions are worthy of note. (*1*) Lithium dialkylcopper reagents react with dithiocarboxylic esters to give tertiary thiols[848] (*2*) Thiono lactones can be converted to cyclic ethers,[849] for example:



This is a valuable procedure because medium and large ring ethers are not easily made, while the corresponding thiono lactones can be prepared from the readily available lactones (see, e.g., **16-63**) by reaction **16-11**.

A terminal alkyne can be converted to the anion under electrolytic conditions, in the presence of CO_2, to give propargylic acids, R—C≡C—COOH.[850]

Aldimines can be converted to secondary amines by treatment with Grignard reagents.[851] Ketimines generally give reduction instead of addition. However, organolithium compounds give the normal addition product with both aldimines and ketimines.[852] For the addition of an organometallic compound to an imine to give a primary amine, R′ in RCH=NR′ would have to be H, and such compounds are seldom stable. However, the conversion has been done, for R = aryl, by the use of the masked reagents $(ArCH{=}N)_2SO_2$ [prepared from an aldehyde RCHO and sulfamide $(NH_2)_2SO_2$]. Addition of R^2MgX or R^2Li to these compounds gives $ArCHR^2NH_2$ after hydrolysis.[853] An intramolecular version of the addition or organolithium reagents is known, and treatment of the *N*-(3-chloropropyl)aldimine of benzaldehyde with lithium and DTBB, followed by hydrolysis with water, gave 2-phenylpyrrolidine.[854] Grignard regents add to imines in the presence of various transition metal catalysts, including $Sc(OTf)_3$[855] or Cp_2ZrCl_2.[856] When chiral additives are used in conjunction with the organolithium reagent, chiral amines are produced[857] with good asymmetric induction.[858] Chiral auxiliaries have been used in addition reactions to imines,[859] and to oxime derivatives.[860] Chiral catalysts lead to enantioselective addition of alkynes to imines to give a homopropargylic amine.[861]

Zinc metal reacts with allylic bromides to form an allylic zinc complex, which reacts with imines to give the homoallylic amine.[862] This reaction is catalyzed by TMSCl.[863] Allylzinc bromide adds to imines.[864] Dialkylzinc reagents add to imines to give the amine, and in the presence of a chiral ligand the reaction proceeds with

good enantioselectivity.[865] Dialkylzinc reagents add to *N*-tosyl imines using a copper catalyst, and with a chiral ligand leads to good enantioselectivity.[866] α-Bromo esters are converted to an organometallic reagent with Zn/Cu, and addition to *N*-arylimines gives *N*-aryl β-amino esters.[867] The reaction of imines, such as ArN=CHCO$_2$Et, where R = a chiral benzylic substituent, and ZnBr$_2$, followed by R′ZnBr leads to a chiral α-amino ester.[868] Terminal alkynes add to imines using ZnCl$_2$ and TMSCl, and with a chiral ligand attached to nitrogen the reaction proceeds with some enantioselectivity.[869]

Other organometallic compounds,[870] including allylic stannanes,[871] allylic samarium, [872] allylic germanium,[873] and allylic indium compounds[874] add to aldimines in the same manner. Aryltrialkylstannanes also add the aryl group to *N*-tosyl imines using a rhodium catalyst and sonication.[875] Catalytic enantioselective addition reactions are well known,[876] including reactions in an ionic liquid.[877] Allylic

[877]In bmim BF$_4$, 1-butyl-3-methylimidazolium tetrafluoroborate: Chowdari, N.S.; Ramachary, D.B.; Barbas III, C.F. *Synlett* ***2003***, 1906.

halides react with imines in the presence of indium metal[878] or $InCl_3$[879] to give the homoallylic amine, and with *N*-sulfonyl imines to give the homoallylic sulfonamide.[880] In this latter reaction, antiselectivity was observed when the reaction was done in water, and syn selectivity when done in aqueous THF.[881] Propargylic halides add to imines in the presence of indium metal, in aq. THF.[882] Imines react with allylic halides and gallium metal, with ultrasound.[883] Imines also react with allylic halides and Yb, in the presence of Me_3SiCl.[884] Aryl iodides add to *N*-aryl imines in the presence of a rhodium catalyst.[885] Titanium enolates add to imines to give β-amino esters.[886] Terminal alkynes react with aryl aldehydes and aryl amines to give propargylic amine without a catalyst,[887] and an iridium[888] or a copper catalyst[889] also leads to a propargylic amine.[890] Terminal alkynes add to imines to give a propargylic amine with high enantioselectivity using a chiral copper complex.[891] Triethylaluminum adds an ethyl group to an imine in the presence of a europium catalyst. Reaction with $PhSnMe_3$ and *N*-tosylimines with a rhodium catalyst, for example, leads to addition of a phenyl group to the carbon of the C=N bond.[892] Other *N*-sulfonyl imines react similarly to give the corresponding sulfonamide, and in the presence of a chiral ligand the reaction proceeds to good enantioselectivity.[893] *N*-Tosyl imines also react with dialkylzinc reagents, giving the sulfonamide with modest enantioselectivity.[894] *N*-Sulfinyl imines, $R_2CH{=}NS({=}O)R'$,[895] react with Grignard reagents (R^2MgX) to give the corresponding *N*-sulfinylamine, $R_2CH(R^2)NHS({=}O)R'$.[896] Enolate anions, generated by reaction of dimethylaminopyridine and a conjugated ketone, add to *N*-tosylimines.[897] *N*-Carbamoyl imines add acetonitrile (via carbon) using DBU and a ruthenium catalyst.[898]

Activated aromatic compounds add to *N*-carbamoyl imines in the presence of copper catalysts, and with good enantioselectivity when a chiral catalyst is used.[899] A combination of $AuCl_3$/AgOTf facilitates the addition of arenes to *N*-tosyl imines.[900] Furan derivatives add via C-2 with good enantioselectivity using a chiral phosphoric acid catalyst.[901] Alkenes add to *N*-tosyl imines with a Yb catalyst[902] an allenes add to *N*-carbamoyl imines in the presence of vanadium catalyst.[903] *N*-Carbamoyl imines, formed *in situ*, react with allylic silanes in the presence of an iodine catalyst.[904] The intramolecular addition of an alkene to an imine, facilitated by Cp_2ZrBu_2, gave a cycloalkyl amine.[905]

Arylboronates (p. 815) add to *N*-sulfonyl imines in the presence of a rhodium catalyst to give the corresponding sulfonamide.[906] Vinyl boronates also add to nitrones in the presence of Me_2Zn, transferring the vinyl group to the C=N unit.[907] Aryl boronic acids (p. 815) add the aryl group to *N*-tosyl imines using a rhodium catalyst.[908] Allylic boronates also add to aldehydes, and subsequent treatment with ammonia give the homoallylic amine.[909]

Allylic silanes, such as allyltrimethylsilane, add to *N*-substituted imines in the presence of a palladium catalyst to give the homoallylic amine.[910] Similar results are obtained when the allylic silane and imine are treated with a catalytic amount of tetrabutylammonium fluoride.[911] *N*-Tosyl imines also react with allylic silanes, and the reaction of $EtO_2C{-}CH{=}NTs$ and allyltrimethylsilane with a chiral copper catalyst gave $EtO_2C{-}CH(NHTs)CH_2CH{=}CH_2$, albeit in poor yield with modest enantioselectivity.[912] Another addition reaction converts aryl aldehydes to the imine using $Me_2N{-}SiMe_3$ and $LiClO_4$, and subsequent reaction with $Me_2PhSiCl$ gave the corresponding amine, $ArCH(SiMe_2Ph)NMe_2$.[913] Allylic trichlorosilanes add to hydrazones to give homoallylic hydrazine derivatives with excellent anti-selectivity[914]

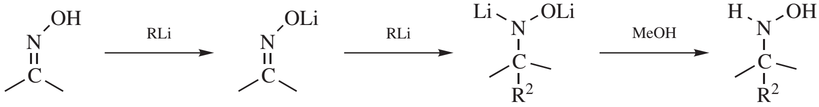
and with good enantioselectivity using a chiral ligand.[915] Chiral allyl silane derivatives have been developed, and add to hydrazones with good enantioselectivity.[916]

Aldehydes add via the α-carbon using proline, to give β-amino aldehydes with good selectivity to give chiral β-amino aldehydes.[917] Silyl enol ethers add to hydrazones in the presence of ZnF_2 and a chiral ligand to give chiral β-hydrazino ketones.[918] Nitro compounds add to *N*-carbamoyl imines with a chiral diamine catalyst with some enantioselectivity.[919] Nitro compounds add via carbon using a copper catalyst, and with good enantioselectivity when a chiral ligand is used.[920] Similar addition to imine derivatives was accomplished using ketene silyl acetals and Amberlyst-15.[921] Alternatively, an imine is reacted first with $Zn(OTf)_2$ and then with a ketene silyl acetal.[922] The conjugate bases of nitro compounds (formed by treatment of the nitro compound with BuLi) react with Grignard reagents in the presence of $ClCH{=}NMe_2^+\ Cl^-$ to give oximes: $RCH{=}N(O)OLi + R'MgX \rightarrow RR'C{=}NOH$.[923]



37

Many other C=N systems (phenylhydrazones, oxime ethers, etc.) give normal addition when treated with Grignard reagents; others give reductions; others give miscellaneous reactions. Organocerium reagents add to hydrazones.[924] Oximes can be converted to hydroxylamines (**37**) by treatment with 2 equivalents of an alkyllithium reagent, followed by methanol.[925] Oxime ethers add an allyl group upon reaction with allyl bromide and indium metal in water.[926] Nitrones, $R_2C{=}N^+(R')–O^-$, react with allylic bromides and Sm to give homoallylic oximes,[927] and with terminal alkynes and a zinc catalyst to give propargylic oximes.[928]

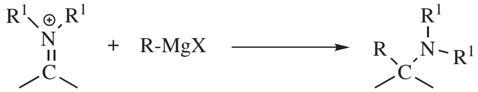
Grignard reagents also add to nitrones.[929] Nitrones react with $CH_2{=}CHCH_2InBr$ in aq. DMF to give the homoallylic oxime[930] and silyl ketene acetals add in the presence of a chiral titanium catalyst to good enantioselectivity.[931] Hydrazone derivatives react with iodoalkenes in the presence of $InCl_3$ and $Mn_2(CO)_{10}$ under photochemical conditions to give the hydrazine derivative.[932] Indium metal promotes the addition of alkyl iodides to hydrazones.[933] A hydrazone can be formed *in situ* by reacting an aldehyde with a hydrazine derivative, and in the presence of tetrallyltin and a scandium catalysts, homoallylic hydrazine derivatives are formed.[934] Ketene dithioacetals add to hydrazones using a chiral zirconium catalyst to give a pyrazolidine.[935]

Radical addition to imines is known. Carbon-centered radicals add to imines.[936] The reaction of an alkyl halide with BEt_3 in aqueous methanol, for example, gives the imine addition product, an alkylated amine.[937] Secondary alkyl iodides add to *O*-alkyl oximes in the presence of BEt_3 and AIBN, and this methodology was used to convert $MeO_2C{-}CH{=}NOBn$ to $MeO_2C{-}CH(R)NOBn$.[938] Benzylic halides adds to imines under photochemical conditions, and in the presence of 1-benzyl-1,4-dihydronicotinamide[939] or with BEt_3 in aqueous methanol.[940] Tertiary alkyl iodides add to oxime ethers using $BF_3{\bullet}OEt_2$ in the presence of BEt_3/O_2.[941]

Iminium salts[942] give tertiary amines directly, with just R adding:



Chloroiminium salts $ClCH{=}NR'_2\ Cl^-$ (generated *in situ* from an amide $HCONR'_2$ and phosgene $COCl_2$) react with 2 equivalents of a Grignard reagent RMgX, one adding to the C=N and the other replacing the Cl, to give tertiary amines $R_2CHNR'_2$.[943]

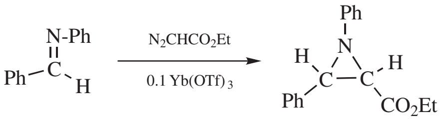
16-32 Addition of Carbenes and Diazoalkanes to C=N Compounds

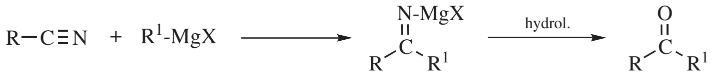
In the presence of metal catalysts such as $Yb(OTf)_3$, diazoalkanes add to imines to generate aziridines. An example is:[944]



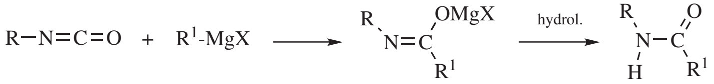
The reaction is somewhat selective for the cis-diastereomer. The use of chiral additives in this reaction leads to aziridines enantioselectively.[945] Imines can be formed by the reaction of an aldehyde and an amine, and subsequent treatment with Me_3SiI and butyllithium gives an aziridine.[946] *N*-Tosyl imines react with diazoalkenes to form *N*-tosyl aziridines, with good cis-selectivity[947] and modest enantioselectivity in the presence of a chiral copper catalyst,[948] but excellent enantioselectivity with a chiral rhodium catalyst.[949]. It is noted that *N*-tosyl aziridines are formed by the reaction of an alkene with PhI=NTs and a copper catalyst.[950] The reaction of alkenes with diazo compounds is discussed in **15-53**.

16-33 The Addition of Grignard Reagents to Nitriles and Isocyanates

Alkyl,oxo-de-nitrilo-tersubstitution (Overall transformation)



***N*-Hydro-*C*-alkyl-addition**



Ketones can be prepared by addition of Grignard reagents to nitriles, followed by hydrolysis of the initially formed imine anion. Many ketones have been made in this manner, though when both R groups are alkyl, yields are not high.[951] Yields

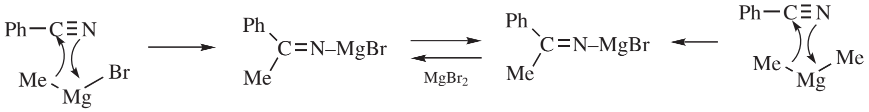
can be improved by the use of Cu(I) salts[952] or by using benzene containing one equivalent of ether as the solvent, rather than ether alone.[953] The ketimine salt does not in general react with Grignard reagents: Hence tertiary alcohols or tertiary alkyl amines are not often side products.[954] By careful hydrolysis of the salt it is sometimes possible to isolate ketimines,[955]

especially when R and R′ = aryl. The addition of Grignard reagents to the C≡N group is normally slower than to the C=O group, and cyano group containing aldehydes add the Grignard reagent without disturbing the CN group.[956] Other metal compounds have been used, including Sm with allylic halides[957] and organocerium compounds such as $MeCeCl_2$.[958] Allylic halides react with an excess of zinc metal in the presence of 40% $AlCl_3$, and in the presence of a nitrile homoallylic ketones are produced after hydrolysis.[959] Benzonitrile reacts as with iodopropane and a mixture of SmI_2 and NiI_2 catalysts to give 1-phenyl-1-butanone.[960]

Addition of Grignard reagents[961] or organolithium reagents[962] to ω-halo nitriles leads to 2-substituted cyclic imines.

The following mechanism has been proposed for the reaction of the methyl Grignard reagent with benzonitrile:[963]



Arenes add to nitriles in the presence of a palladium catalyst in DMSO/trifluoroacetic acid to give a diaryl ketone.[964]

The addition of Grignard reagents to isocyanates gives, after hydrolysis, *N*-substituted amides.[965] This is a very good reaction and can be used to prepare

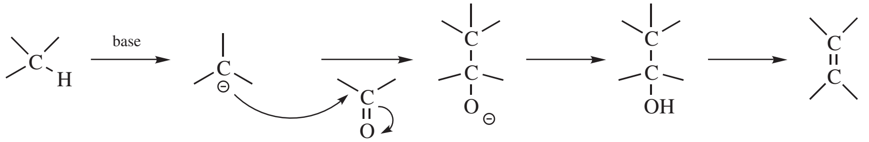
G. Carbon Attack by Active Hydrogen Compounds

Reactions **16-34–16-50** are base-catalyzed condensations (although some of them are also catalyzed to acids).[969] In **16-34–16-44**, a base removes a C—H proton to give a carbanion, which then adds to a C=O. The oxygen acquires a proton, and the resulting alcohol may or may not be dehydrated, depending on whether an α hydrogen is present and on whether the new double bond would be in conjugation with double bonds already present:



The reactions differ in the nature of the active hydrogen component and the carbonyl component. Table 16.2 illustrates the differences. Reaction **16-50** is an analogous reaction involving addition to C≡N.

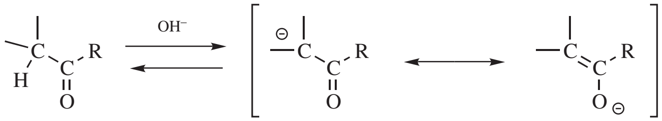
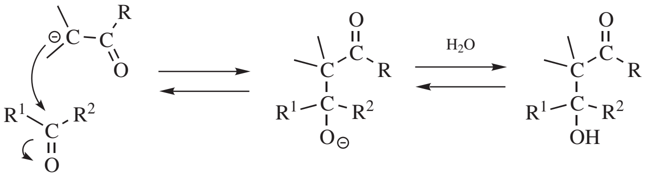
Thorpe reaction			

In the *aldol reaction*,[971] the α carbon of one aldehyde or ketone molecule adds to the carbonyl carbon of another.[972] Although acid-catalyzed aldol reactions are known,[973] the most common form of the reaction uses a base. There is evidence that an SET mechanism can intervene when the substrate is an aromatic ketone.[974] Although hydroxide was commonly used in early versions of this reaction, stronger bases, such as alkoxides (RO^-) or amides (R_2N^-), are also common. Amine bases have been used.[975] Hydroxide ion is not a strong enough base to convert substantially all of an aldehyde or ketone molecule to the corresponding enolate ion, that is., the equilibrium lies well to the left, for both aldehydes and



ketones. Nevertheless, enough enolate ion is present for the reaction to proceed:



[971]This reaction is also called the *aldol condensation*, though, strictly speaking, this term applies to the formation only of the α,β-unsaturated product, and not the aldol.

[972]For reviews, see Thebtaranonth, C.; Thebtaranonth, Y., in Patai, S.; Rappoport, Z. *The Chemistry of Enones*, pt. 1, Wiley, NY, ***1989***, pp. 199–280, 199–212; Hajos, Z.G., in Augustine, R.L. *Carbon–Carbon Bond Formation*, Vol. 1; Marcel Dekker, NY, ***1979***; pp. 1–84; Nielsen, A.T.; Houlihan, W.J. *Org. React.* ***1968***, *16*, 1.

[973]For example, see Mahrwald, R.; Gündogan, B. *J. Am. Chem. Soc.* ***1998***, *120*, 413.

[974]Ashby, E.C.; Argyropoulos, J.N. *J. Org. Chem.* ***1986***, *51*, 472.

[975]Trost, B.M.; Silcoff, E.R.; Ito, H. *Org. Lett.* ***2001***, *3*, 2497.

This equilibrium lies further to the right with alkoxide and especially with amide bases, depending on the solvent. Protic solvents, such as water or alcohol, are acidic enough to react with the enolate anion and shift the equilibrium to the left. In an aprotic solvent, such as ether or THF, with a strong amide base, such as lithium diisopropylamide (LDA, p. 389), the equilibrium lies more to the right.[976] A variety of amide bases can be used to deprotonate the ketone or aldehyde, and in the case of an unsymmetrical ketone removal of the more acidic proton leads to the kinetic enolate anion.[977] Note that a polymer-bound amide base has been used[978] and solid-phase chiral lithium amides are known.[979] A polymer-supported phosphoramide has been used as a catalyst for the aldol condensation.[980] The product is a β-hydroxy aldehyde (called an *aldol*) or ketone, which in some cases is dehydrated during the course of the reaction. In aprotic solvents with a mild workup procedure, however, the aldol is readily isolated unless the substrate is an aromatic aldehyde or ketone. The aldol reaction has been done in ionic liquids.[981] Even if the dehydration is not spontaneous, it can usually be done easily, since the new double bond is in conjugation with the C=O bond; so that this is a method of preparing α,β-unsaturated aldehydes and ketones, as well as β-hydroxy aldehydes and ketones. One-pot procedures have been reported to give the conjugated product.[982] The entire reaction is an equilibrium (including the dehydration step), and α,β-unsaturated and β-hydroxy aldehydes and ketones can be cleaved by treatment with $^-$OH (the *retrograde aldol reaction*). The *retro*-aldol condensation has been exploited for crossed-aldol reactions.[983] A vinylogous aldol reaction is known[984] as is a 1"double" aldol.[985] Enzyme-mediated aldol reactions have been reported using two aldehydes, including formaldehyde.[986]

Under the principle of vinylogy, the active hydrogen can be one in the γ position of an α,β-unsaturated carbonyl compound:

[985]For a discussion of the mechanism of this reaction see Abiko, A.; Inoue, T.; Masamune, S. *J. Am. Chem. Soc.* ***2002***, *124*, 10759.

[986]Demir, A.S.; Ayhan, P.; Igdir, A.C.; Duygu, A.N. *Tetrahedron* ***2004***, *60*, 6509.

The scope of the aldol reaction may be discussed under five headings:

1. *Reaction between Two Molecules of the Same Aldehyde*. Hydroxide or alkoxide bases are used in protic solvents,[987] and the reaction is quite feasible. Many aldehydes have been converted to aldols and/or their dehydration products in this manner. The most effective catalysts are basic ion-exchange resins. Of course, the aldehyde must possess an α hydrogen.
2. *Reaction between Two Molecules of the Same Ketone*. With hydroxide or alkoxide bases in protic solvents the equilibrium lies well to the left,[988] and the reaction is feasible only if the equilibrium can be shifted. This can often be done by allowing the reaction to proceed in a Soxhlet extractor (e.g., see OS **I**, 199). Two molecules of the same ketone can also be condensed without a Soxhlet extractor,[989] by treatment with basic Al_2O_3.[990] Unsymmetrical ketones condense on the side that has more hydrogens. An exception is butanone, which reacts at the CH_2 group with acid catalysts, though with basic catalysts, it too reacts at the CH_3 group.

   Alternatively, the use of an amide base, such as LDA or lithium hexamethyldisilazide (p. 389), in aprotic solvents, such as ether or THF, at low temperatures, generates an enolate anion under conditions where the equilibrium lies more to the right. A second equivalent of the ketone can then be added. Clearly, this technique is effective in reactions of aldehydes.
3. *Reaction between Two Different Aldehydes*. In the most general case, this will produce a mixture of four products (eight, if the alkenes are counted). However, if one aldehyde does not have an α hydrogen, only two aldols are possible, and in many cases the crossed product is the main one. The crossed-aldol reaction is often called the *Claisen–Schmidt reaction*.[991] The crossed aldol is readily accomplished using amide bases in aprotic solvent. The first aldehyde is treated with LDA in THF at −78°C, for example, to form the enolate anion. Subsequent treatment with a second aldehyde leads to the mixed aldol product. The crossed aldol of two aldehydes has been done using potassium *tert*-butoxide and $Ti(OBu)_4$.[992]
4. *Reaction between Two Different Ketones*. This is seldom attempted with hydroxide or alkoxide bases in protic solvents since similar considerations apply to those discussed for aldehydes. This reaction is commonly done with amide bases in aprotic solvents, but with somewhat more difficulty than with aldehydes.

[987]For discussions of equilibrium constants in aldol reactions, see Guthrie, J.P.; Wang, X. *Can. J. Chem.* ***1991***, *69*, 339; Guthrie, J.P. *J. Am. Chem. Soc.* ***1991***, *113*, 7249, and references cited therein.

[988]The equilibrium concentration of the product from acetone in pure acetone was determined to be 0.01%: Maple, S.R.; Allerhand, A. *J. Am. Chem. Soc.* ***1987***, *109*, 6609.

[989]For another method, see Barot, B.C.; Sullins, D.W.; Eisenbraun, E.J. *Synth. Commun.* ***1984***, *14*, 397.

[990]Muzart, J. *Synthesis* ***1982***, 60; *Synth. Commun.* ***1985***, *15*, 285.

[991]For an aqueous version, see Buonora, P.T.; Rosauer, K.G.; Dai, L. *Tetrahedron Lett.* ***1995***, *36*, 4009.

[992]Han, Z.; Yorimitsu, H.; Shinokubo, H.; Oshima, K. *Tetrahedron Lett.* ***2000***, *41*, 4415.

5. *Reaction between an Aldehyde and a Ketone*. This is usually feasible with hydroxide or alkoxides bases in protic solvents, particularly when the aldehyde has no α hydrogen, since there is no competition from ketone condensing with itself.[993] This is also called the *Claisen–Schmidt reaction*. Even when the aldehyde has an α hydrogen, it is generally the α carbon of the ketone that adds to the carbonyl of the aldehyde, not the other way around. Mixtures are usually produced, however. If the ketone or the aldehyde is treated with an amide base in aprotic solvents, a second aldehyde or ketone can be added to give the aldolate with high regioselectivity. The reaction can be also made regioselective by preparing an enol derivative of the ketone separately[994] and then adding this to the aldehyde (or ketone). Other types of preformed derivatives that react with aldehydes and ketones are enamines (with a Lewis acid catalyst),[995] and enol borinates $R'CH{=}CR^2{-}OBR_2$[996] (which can be synthesized by **15-27**) or directly from an aldehyde or ketone[997]). Preformed metallic enolates are also used. For example, lithium enolates[998] (prepared by **12-23**) react with the substrate in the presence of $ZnCl_2$;[999] in this case the aldol product is stabilized by chelation of its two oxygen atoms with the zinc ion.[1000] Other metallic enolates can be used for aldol reactions, either preformed or generated *in situ* with a catalytic amount of a metal compound. Metals used for this purpose include Mg,[1001] Ti,[1002] Zr,[1003] Pd,[1004]

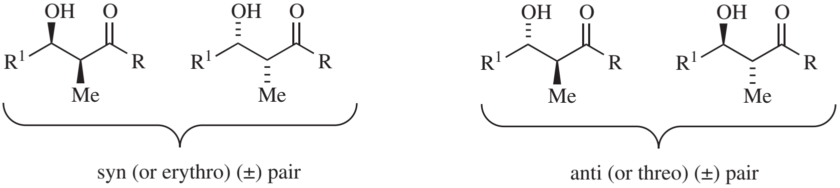
In,[1005] Sn,[1006] La,[1007] and Sm,[1008] all of which give products with moderate to excellent diastereoselectivity[1009] and regioselectivity. α-Alkoxy ketones react with lithium enolates particularly rapidly.[1010] A bis(aldol) condensation has been reported with epoxy ketones and aldehydes using SmI_2.[1011] Vinyl silanes react with aldehydes in the presence of a copper catalyst to vie the aldol product.[1012]

The reactions with preformed enol derivatives provide a way to control the stereoselectivity of the aldol reaction.[1013] As with the Michael reaction (**15-24**), the aldol reaction creates two new stereogenic centers, and, in the most general case, there are four stereoisomers of the aldol product (two racemic diastereomers), which can be represented as



Among the preformed enol derivatives used for diastereoselective aldol condensations have been enolates of Li,[1014] Mg, Ti,[1015] Zr,[343] and Sn,[1016] silyl enol

ethers,[1017] enol borinates,[1018] and enol borates $R'CH{=}CR^2{-}OB(OR)_2$.[1019] The nucleophilicity of silyl enol ethers has been examined.[1020] Base-induced formation of the enolate anion generally leads to a mixture of (*E*)- and (*Z*)-isomers, and dialkyl amide bases are used in most cases. The (E/Z) stereoselectivity depends on the structure of the lithium dialkylamide base, with the highest (E/Z) ratios obtained with LiTMP-butyllithium mixed aggregates in THF.[1021] The use of LiHMDS resulted in a reversal of the (E/Z) selectivity. In general, metallic (*Z*) enolates give the syn (or erythro) pair, and this reaction is highly useful for the diastereoselective synthesis of these products.[1022] The (*E*) isomers generally react nonstereoselectively. However, anti (or threo) stereoselectivity has been achieved in a number of cases, with titanium enolates,[1023] with magnesium enolates,[1024] with certain enol borinates,[1025] and with lithium enolates at −78°C.[1026] Enolization accounts for syn–anti isomerization of aldols.[1027] In another variation, a β-keto Weinreb amide (see **16-82**) reacted with $TiCl_4$ and Hünig's base (iPr$_2$NEt) and then an aldehyde to give the β-hydroxy ketone.[1028]

in catalytic reactions. Aldehydes are condensed with ketones with potassium hexamethyldisilazide (KHMDS) and 8% of a chiral lithium catalyst, giving the aldol product with moderate enantioselectivity.[1043] Structural variations in the aldehyde or ketone are compatible with many enantioselective condensation reactions. An α-hydroxy ketone was condensed with an aldehyde using a chiral zinc catalyst to give the aldol (an α,β-dihydroxy ketone) with good syn selectivity and good enantioselectivity.[1044] A catalytic amount of a nicotine metabolite allows an enantioselective reaction in aqueous media.[1045] Chiral vinylogous aldol reactions have been reported.[1046]

Silyl enol ethers react with aldehydes in the presence of chiral boranes[1047] or other additives[1048] to give aldols with good asymmetric induction (see the Mukaiyama aldol reaction in **16-35**). Chiral boron enolates have been used.[1049] Since both new stereogenic centers are formed enantioselectively, this kind of process is called *double asymmetric synthesis*.[1050] Where both the enolate derivative and substrate were achiral, carrying out the reaction in the presence of an optically active boron compound[1051] or a diamine coordinated with a tin compound[1052] gives the aldol product with excellent enantioselectivity for one stereoisomer. Formation of the magnesium enolate anion of a chiral amide, adds to aldehydes to give the alcohol enantioselectively.[1053]

Diamine protonic acids have been used for catalytic asymmetric aldol reaction.[1054] Boron triflate derivatives, R_2BOTf, have been used for the condensation of ketals and ketone to give β-alkoxy ketones.[1055]

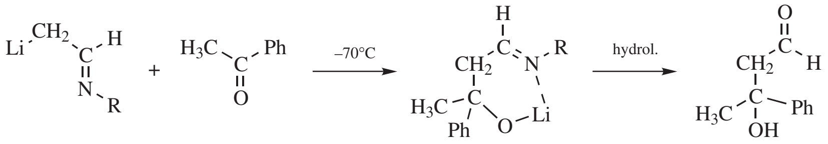
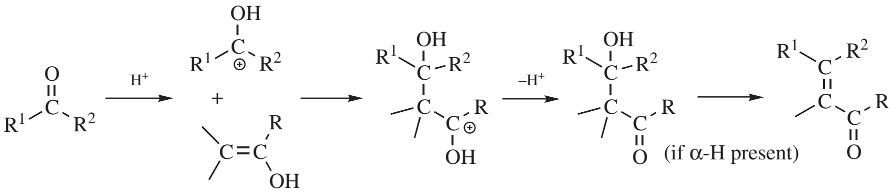
It is possible to make the α carbon of the aldehyde add to the carbonyl carbon of the ketone, by using an imine instead of an aldehyde, and LiN(*i*Pr)$_2$ as the base:[1056]



This is known as a *directed aldol reaction*. Similar reactions have been performed with α-lithiated dimethylhydrazones of aldehydes or ketones[1057] and with α-lithiated aldoximes.[1058]

The aldol reaction can also be performed with acid catalysts, as mentioned above, in which case dehydration usually follows. Here, there is initial protonation of the carbonyl group, which attacks the α carbon of the *enol* form of the other molecule:[1059]



With respect to the enol, this mechanism is similar to that of halogenation (**12-4**). A side reaction that is sometimes troublesome is further condensation, since the product of an aldol reaction is still an aldehyde or ketone. The aldol condensation of aldehydes has also been done using a mixture of pyrrolidine and benzoic acid.[1060]

The intramolecular aldol condensation is well known, and aldol reactions are often used to close five- and six-membered rings. Because of the favorable entropy (p. 303), such ring closures generally take place with ease[1061] when using hydroxide or alkoxide bases in protic solvents. In aprotic solvents with amide bases,

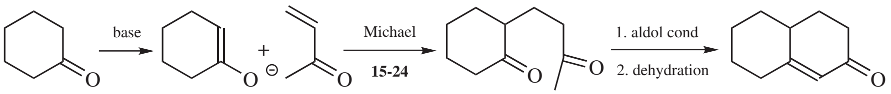
[1061]For rate and equilibrium constants, see Guthrie, J.P.; Guo, J. *J. Am. Chem. Soc.* ***1996***, *118*, 11472. For neighboring-group effects, see Eberle, M.K. *J. Org. Chem.* ***1996***, *61*, 3844.

formation of the enolate anion occurs by deprotonation of the more acidic site, followed by cyclization to the second carbonyl. The acid-catalyzed intramolecular aldol condensation is known, and the mechanism has been studied.[1062] Stereoselective proline-catalyzed intramolecular aldol reactions give the cyclize product with good enantioselectivity.[1063]

An important extension of the intramolecular aldol condensation is the *Robinson annulation* reaction,[1064] which has often been used in the synthesis of steroids and terpenes. In original versions of this reaction, a cyclic ketone is converted to another cyclic ketone under equilibrium conditions using hydroxide or alkoxide bases in a protic solvent, forming one additional six-membered ring containing a double bond. The reaction can be done in a stepwise manner using amide bases in aprotic solvents. In the reaction with hydroxide or alkoxide bases in alcohol or water solvents, the substrate is treated with methyl vinyl ketone (or a simple derivative of methyl vinyl ketone) and a base.[1065] The enolate ion of the substrate adds to the methyl vinyl ketone in a Michael reaction (**15-24**) to give a diketone that undergoes or is made to undergo an internal aldol



reaction and subsequent dehydration to give the product.[1066] The Robinson annulation can be combined with alkylation.[1067] Enantioselective Robinson annulation techniques have been developed, including a proline-catalyzed reaction.[1068] The Robinson annulation has been done in ionic liquids[1069] and a solvent-free version of the reaction is known.[1070]

Because methyl vinyl ketone has a tendency to polymerize, precursors are often used instead, that is., compounds that will give methyl vinyl ketone when treated with a base. One common example, $MeCOCH_2CH_2NEt_2Me^+ I^-$ (see **17-9**), is easily prepared by quaternization of $MeCOCH_2CH_2NEt_2$, which itself is prepared

by a Mannich reaction (**16-19**) involving acetone, formaldehyde, and diethylamine. α-Silylated vinyl ketones $RCOC(SiMe_3){=}CH_2$ have also been used successfully in annulation reactions.[1071] The $SiMe_3$ group is easily removed. 1,5-Diketones prepared in other ways are also frequently cyclized by internal aldol reactions. When the ring closure of a 1,5-diketone is catalyzed by the amino acid (*S*)-proline, the product is optically active with high enantiomeric excess.[1072] *Stryker's reagent* [1073]$[(Ph_3P)CuH]_6$ has been used for an intramolecular addition where ketone enolate anion to a conjugated ketone, giving cyclic alcohol with a pendant ketone unit.[1074]

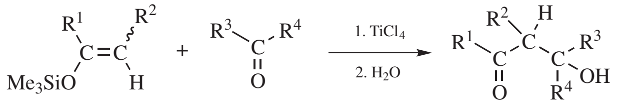
16-35 Mukaiyama Aldol and Related Reactions[1075]

***O*-Hydro-*C*-(α-acylalkyl)-addition**

An important variation of the aldol condensation involves treatment of an aldehyde or ketone with a silyl ketene acetal $R_2C{=}C(OSiMe_3)OR'$[1076] in the presence of $TiCl_4$[1077], to give **38**. The silyl ketene acetal can be considered a preformed enolate that gives aldol product



38

with $TiCl_4$ in aqueous solution, or with no catalyst at all.[1078] A combination of $TiCl_4$ and a *N*-tosyl imine has also been used to facilitate the Mukaiyama aldol

RCH=CH(OTMS)$SiMe_3$ react with acetals in the presence of $SnCl_4$ to give β-alkoxy silyl ketones.[1104]

An interesting variation in this reaction combined an intermolecular Mukaiyama aldol followed by an intramolecular reaction (a "domino" Mukaiyama aldol) that gave cyclic conjugated ketone products.[1105] Borane derivatives such as C=C—OB$(NMe_2)_2$ react with aldehydes to give β-amino ketones.[1106]

Silyl enol ethers[1107] derived from esters (silyl ketene acetals) react with aldehydes in the presence of various catalysts to give β-hydroxy esters. Water accelerates the reaction of an aldehyde and a ketene silyl acetal with no other additives.[1108] The reaction is catalyzed by triphenylphosphine[1109] and also by $SiCl_4$ with a chiral bis(phosphoramide) catalyst.[1110] The reaction was done without a catalyst in an ionic liquid.[1111] A vinylogous reaction is known that gives δ-hydroxy-α,β-unsaturated esters.[1112] Under different conditions, silyl ketene acetals of conjugated esters react with aldehydes to give conjugated lactones.[1113] Imines react with silyl ketene acetals in the presence of SmI_3 to give β-amino esters.[1114] Another variation converted a *N*-(1-trimethylsilyloxyvinyl) imine to a conjugated amide by initial reaction with 2 equivalents of *n*-butyllithium and a zirconium complex followed by reaction with an aldehyde.[1115] Silyl ketene acetals also undergo conjugate addition in reactions with conjugated ketones.[1116] Silyl ketene acetals of thio esters also react with aldehydes to give β-hydroxy thioesters.[1117]

Asymmetric Mukaiyama aldol reactions and reactions of silyl ketene acetals have been reported, [1118] usually using chiral additives[1119] although chiral auxiliaries

have also been used.[1120] Chiral catalysts, usually transition-metal complexes using chiral ligands, are quite effective,[1121] but chiral bis(oxazolones)[1122] and chiral quaternary ammonium salts[1123] have also been used. A zirconium BINOL complex gave good enantioselectivity in reactions of silyl ketene acetals, and also good anti selectivity in the product.[1124] This reaction can also be run with the aldehyde or ketone in the form of its acetal $R^3R^4C(OR')_2$, in which case the product is the ether $R^1COCHR_2CR^3R^4OR'$ instead of **38**.[1125] Trichlorosilyl enol ethers react with aldehydes directly in the presence of a chiral phosphoramide to give the aldol with good syn selectivity and good enantioselectivity.[1126] Vinylogous silyl ketene acetals with a chiral oxazolidinone auxiliary attached to the α-vinylic carbon react with aldehydes and $TiCl_4$ to give a δ-hydroxy-α,β-unsaturated amide (an acyl oxazolidinone).[1127]

Enol acetates and enol ethers also give this product when treated with acetals and $TiCl_4$ or a similar catalyst.[1128] A variation of this condensation uses an enol acetate with an aldehyde in the presence of Et_2AlOEt to give the aldol product.[1129]

In the presence of a strong base, the α carbon of a carboxylic ester or other acid derivative can condense with the carbonyl carbon of an aldehyde or ketone to give a β-hydroxy ester,[1130] amide, and so on., which may or may not be dehydrated to the α,β-unsaturated derivative. This reaction is sometimes called the *Claisen reaction*,[1131] an unfortunate usage since that name is more firmly connected to **16-85**. Early reactions used hydroxide or an alkoxide base in water or alcohol solvents, where self-condensation was the major process. Under such conditions, the aldehyde or ketone was usually chosen for its lack of an α-proton. Much better control of the reaction was achieved when amide bases in aprotic solvents, such as ether or THF, were used. The reaction of *tert*-butyl acetate and LDA[1132] in hexane or more commonly THF at −78°C gives the enolate anion of *tert*-butyl acetate,[1133] (**12-23**, e.g., although self-condensation is occasionally a problem even here. Subsequent reaction a ketone provides a simple rapid alternative to the Reformatsky reaction (**16-28**) as a means of preparing β-hydroxy *tert*-butyl esters. It is also possible for the α carbon of an aldehyde or ketone to add to the carbonyl carbon of a carboxylic ester, but this is a different reaction (**16-86**) involving nucleophilic substitution and not addition to a C=O bond. It can, however, be a side reaction if the aldehyde or ketone has an α hydrogen.

Transition-metal mediated condensation of esters and aldehydes is known. The reaction of a thioester and an aryl aldehyde with $TiCl_4$—NBu_3, for example, gave a β-hydroxy thioester with good syn selectivity.[1134] Selenoamides [$RCH_2C(=Se)NR'_2$] react with LDA and then an aldehyde to give β-hydroxy selenoamides.[1135]

Besides ordinary esters (containing an α hydrogen), the reaction can also be carried out with lactones and, as in **16-34**, with the γ position of α,β-unsaturated esters (vinylogy). The enolate anion of an amide can be condensed with an aldehyde.[1136]

There are a number of variations of the condensation reaction of acid derivatives. The reaction between a cyclic ketone having a pendant alkynyl ester unit and tetrabutylammonium fluoride leads to cyclization to a bicyclic alcohol with an exocyclic allene moiety.[1137] A chain-extension reaction culminates in acyl addition of an ester enolate. The reaction of a β-keto ester, such as methyl 3-oxobutanote and $EtZnCH_2I$, leads to chain extension via a carbenoid-like insertion reaction (p. 803), which reacts with an aldehyde in a second step to give a methyl 3-oxopentanoate derivative with a —CH(OH)R group at C-2 relative to the ester carbonyl.[1138]

[1130]If the reagent is optically active because of the presence of a chiral sulfoxide group, the reaction can be enantioselective. For a review of such cases, see Solladié, G. *Chimia* ***1984***, *38*, 233.

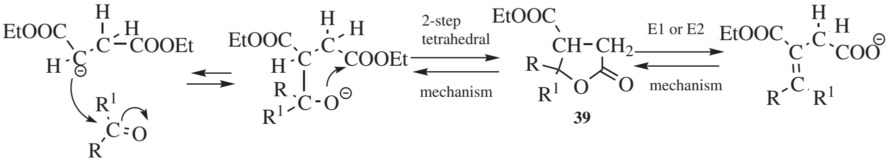
For most esters, a much stronger base is needed than for aldol reactions; $(i\text{Pr})_2$-NLi (LDA, p. 389), Ph_3CNa and $LiNH_2$ are among those employed. However, one type of ester reacts more easily, and such strong bases are not needed: diethyl succinate and its derivatives condense with aldehydes and ketones in the presence of bases such as NaOEt, NaH, or $KOCMe_3$. This reaction is called the *Stobbe condensation*.[1139] One of the ester groups (sometimes both) is hydrolyzed in the course of the reaction. The following mechanism accounts for (*1*) the fact the succinic esters react so much better than others; (*2*) one ester group is always cleaved; and (*3*) the alcohol is not the product but the alkene. In addition, intermediate lactones **39** have been isolated from the mixture.[1140] The Stobbe condensation has been extended to di-*tert*-butyl esters of glutaric acid.[1141] The boron-mediated reaction is known.[1142]



Chiral additives, such as diazaborolidines can be added to an ester, and subsequent treatment with a base and then an aldehyde leads to a chiral β-hydroxy ester.[1143] A variety of chiral amide or oxazolidinone derivatives have been used to form amide linkages to carboxylic acid derivatives. These chiral auxiliaries lead to chirality transfer from the enolate anion of such derivatives, in both alkylation reactions and acyl substitution reactions with aldehydes and ketones. The so-called Evans auxiliaries (**40-42**) are commonly used and give good enantioselectivity.[1144] A variation is the magnesium halide-catalyzed anti-aldol reaction of chiral *N*-acylthiazolidinethiones (see **43**).[1145] The use of chiral *N*-acyloxazolidinthiones with $TiCl_4$ and sparteine also gave good selectivity in the acyl addition.[1146] Chiral diazaboron derivatives have also been used to facilitate the condensation of a α-phenylthio ester with an aldehyde.[1147]

16-37 The Henry Reaction[1149]

$$CH_3NO_2 + HCHO \xrightarrow{^-OH} HOCH_2CH_2NO_2$$

When aliphatic nitro compounds are used instead of aldehydes or ketones, no reduction occurs, and the reaction has been referred to as a Tollens' reaction (see **16-43**). However, the classical condensation of an aliphatic nitro compound with an aldehyde or ketone is usually called the *Henry reaction*[1150] or the *Kamlet reaction*, and is essentially a nitro aldol reaction. A variety of conditions have been reported, including the use of a silica catalyst,[1151] Mg—Al hydrotalcite,[1152] a tetraalkylammonium hydroxide,[1153] proazaphosphatranes,[1154] or an ionic liquid.[1155] A solvent free Henry reaction was reported in which a nitroalkane and an aldehyde were reacted on KOH powder.[1156] Potassium phosphate has been used with nitromethane and aryl aldehydes.[1157] The Henry reaction has been done using $ZnEt_2$ and 20% ethanolamine.[1158] A gel-entrapped base has been used to catalyze this reaction.[1159]

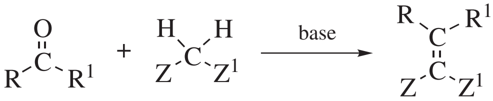
Catalytic enantioselective Henry reactions are known,[1160] such as the use of a chiral copper catalyst[1161] or a zinc catalyst.[1162] The Henry reaction of nitromethane an a chiral aldehyde under high pressure gives the β-nitro alcohol with excellent enantioselectivity.[1163]

A variation of this reaction converts nitro compounds to nitronates $RCH{=}N^+(OTMS){-}O^-$, which react with aldehydes in the presence of a copper catalyst to give the β-nitro alcohol.[1164]

16-38 The Knoevenagel Reaction

Bis(ethoxycarbonyl)methylene-de-oxo-bisubstitution, and so on



The condensation of aldehydes or ketones, usually not containing an α hydrogen, with compounds of the form Z—CH_2—Z′ or Z—CHR—Z′ is called the *Knoevenagel reaction*.[1165] Both Z and Z′ may be CHO, COR, COOH, COOR, CN, NO_2, SOR, SO_2R, SO_2OR, or similar groups. Such compounds have a significantly higher enol content[1166] and the α-proton is much more acidic (Table 8.1 on p. 360). When Z = COOH, decarboxylation of the product often takes place *in situ*.[1167] If a strong enough base is used, the reaction can be performed on compounds possessing only a single Z (e.g., CH_3Z or RCH_2Z). Other active hydrogen compounds can also be employed, among them $CHCl_3$, 2-methylpyridines, terminal acetylenes, cyclopentadienes, and so on.; in fact any compound that contains a C—H bond the hydrogen of which can be removed by a base. As shown in the example, the reaction of β-keto esters and aldehydes to give **44** is promoted by diethylamine at 0°C. Nitroalkanes[1149] as well as β-keto sulfoxides[1168] undergo the reaction.

As with **16-34**, these reactions have sometimes been performed with acid catalysts.[1169] Ionic liquid solvents have been used,[1170] and heating on quaternary ammonium salts without solvent leads to a Knoevenagel reaction.[1171] Other solvent-free reactions are known.[1172] Ultrasound has been used to promote the reaction,[1173] and it has also been done using microwave irradiation[1174] or on silica,[1175] with microwave irradiation. Another solid-state variation is done on moist LiBr,[1176] heating with sodium carbonate and molecular sieves 4 Å promotes the reaction,[1177] as do zeolites.[1178] High-pressure conditions have been used.[1179] Transition-metal compounds such as palladium complexes,[1180] SmI_2[1181] or $BiCl_3$[1182] have been used to promote the Knoevenagel reaction.

In the reaction with terminal acetylenes,[1183] sodium acetylides are the most common reagents (when they are used, the reaction is often called the *Nef reaction*), but lithium,[1184] magnesium, and other metallic acetylides have also been used. A particularly convenient reagent is lithium acetylide–ethylenediamine complex,[1185] a stable, free-flowing powder that is commercially available. Alternatively, the substrate may be treated with the alkyne itself in the presence of

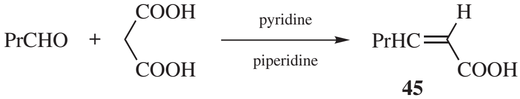
a base, so that the acetylide is generated *in situ*. This procedure is called the *Favorskii reaction*, not to be confused with the Favorskii rearrangement (**18-7**).[1186]

With most of these reagents the alcohol is not isolated (only the alkene) *if* the alcohol has a hydrogen in the proper position.[1187] However, in some cases the alcohol is the major product. A β-keto allylic ester was shown to react with an aldehyde to give a β-hydroxy ketone, with loss of the allyl ester moiety, upon treatment with $YbCl_3$ and a palladium catalyst.[1188] With suitable reactants, the Knoevenagel reaction, like the aldol (**16-2**), has been carried out diastereoselectively[1189] and enantioselectively.[1190] When the reactant is of the form ZCH_2Z', aldehydes react much better than ketones and few successful reactions with ketones have been reported. However, it is possible to get good yields of alkene from the condensation of diethyl malonate, $CH_2(COOEt)_2$, with ketones, as well as with aldehydes, if the reaction is run with $TiCl_4$ and pyridine in THF.[1191] In reactions with ZCH_2Z', the catalyst is most often a secondary amine (piperidine is the most common, but see formation of **44**), though many other catalysts have been used. When the catalyst is pyridine (to which piperidine may or may not be added) the reaction is known as the *Doebner modification* of the Knoevenagel reaction and the product is usually the conjugated acid **45**. Alkoxides are also common catalysts. Microwave-induced Doebner condensation reactions are known.[1192]



45

A number of special applications of the Knoevenagel reaction follow:

1. The dilithio derivative of *N*-methanesulfinyl-*p*-toluidine[1193] (**46**) adds to aldehydes and ketones to give, after hydrolysis, the hydroxysulfinamides

[1186]For a discussion of the mechanism of the Favorskii addition reaction, see Kondrat'eva, L.A.; Potapova, I.M.; Grigina, I.N.; Glazunova, E.M.; Nikitin, V.I. *J. Org. Chem. USSR* ***1976***, *12*, 948.

[1196]Yoda, H.; Ujihara, Y.; Takabe, K. *Tetrahedron Lett.* ***2001***, *42*, 9225.

[1197]For reviews of α-metalated isocyanides, see Schöllkopf, U. *Pure Appl. Chem.* ***1979***, *51*, 1347; *Angew. Chem. Int. Ed.* ***1977***, *16*, 339; Hoppe, D. *Angew. Chem. Int. Ed.* ***1974***, *13*, 789.

When the reaction is run with potassium *tert*-butoxide in THF at −5°C, one obtains (after hydrolysis) the normal Knoevenagel product **49**, except that the isocyano group has been hydrated (**16-97**).[1198] With the same base but with 1,2-dimethoxyethane (DME) as solvent the product is the nitrile **50**.[1199] When the ketone is treated with **48** and thallium(I) ethoxide in a 4:1 mixture of absolute ethanol and DME at room temperature, the product is a 4-ethoxy-2-oxazoline **51**.[1200] Since **50** can be hydrolyzed[1201] to a carboxylic acid[1198] and **51** to an α-hydroxy aldehyde,[1200] this versatile reaction provides a means for achieving the conversion of RCOR′ to RCHR′COOH, RCHR′CN, or RCR′(OH)CHO. The conversions to RCHR′COOH and to RCHR′CN[1202] have also been carried out with certain aldehydes (R′ = H).

3. Aldehydes and ketones RCOR′ react with α-methoxyvinyllithium, $CH_2{=}C(Li)OMe$, to give hydroxy enol ethers, $RR'C(OH)C(OMe){=}CH_2$, which are easily hydrolyzed to acyloins, RR′C(OH)COMe.[1203] In this reaction, the $CH_2{=}C(Li)OMe$ is a synthon for the unavailable $H_3C{-}\overset{\ominus}{C}{=}O$,[1204] and is termed an *acyl anion equivalent*. The reagent also reacts with esters RCOOR′ to give $RC(OH)(COMe{=}CH_2)_2$. A synthon for the Ph—C=O ion is $PhC(CN)OSiMe_3$, which adds to aldehydes and ketones RCOR′ to give, after hydrolysis, the α-hydroxy ketones, RR′C(OH) *C(OH)COPh.*[1205]

4. Lithiated allylic carbamates (**52**) (prepared as shown) react with aldehydes or ketones (R^6COR^7), in a reaction accompanied by an allylic rearrangement, to give (after hydrolysis) γ-hydroxy aldehydes or ketones.[1206] The reaction is called *the homoaldol reaction*, since the product is a homolog of the product of **16-34**. The reaction has been performed enantioselectively.[1207]

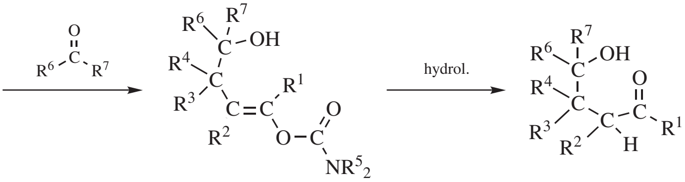
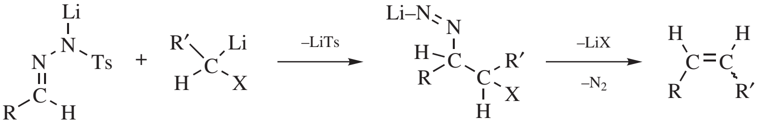
52



5. The lithium salt of an active hydrogen compound adds to the lithium salt of the tosylhydrazone of an aldehyde to give product **53**. If X = CN, SPh, or SO_2R, **53** spontaneously loses N_2 and LiX to give the alkene **54**. The entire process is done in one reaction vessel: The active hydrogen compound is mixed with the tosylhydrazone and the mixture is treated with (iPr)$_2$NLi to form both salts at once.[1208] This process is another alternative to the Wittig reaction for forming double bonds.



53 **54**

16-39 The Perkin Reaction

α-Carboxyalkylidene-de-oxo-bisubstitution

The condensation of aromatic aldehydes with anhydrides is called the *Perkin reaction*.[1209] When the anhydride has two α hydrogens (as shown), dehydration

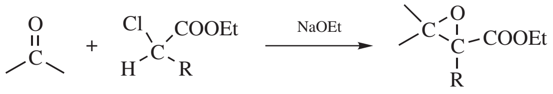
[1208] Vedejs, E.; Dolphin, J.M.; Stolle, W.T. *J. Am. Chem. Soc.* ***1979***, *101*, 249.
[1209] For a review, see Johnson, J.R. *Org. React.* ***1942***, *1*, 210.

always occurs; the β-hydroxy acid salt is never isolated. In some cases, anhydrides of the form $(R_2CHCO)_2O$ have been used, and then the hydroxy compound is the product since dehydration cannot take place. The base in the Perkin reaction is nearly always the salt of the acid corresponding to the anhydride. Although the Na and K salts have been most frequently used, higher yields and shorter reaction times have been reported for the Cs salt.[1210] Besides aromatic aldehydes, their vinylogs ArCH=CHCHO also give the reaction. Otherwise, the reaction is not suitable for aliphatic aldehydes.[1211]

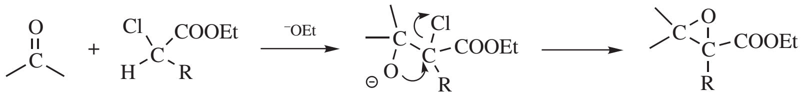
OS **I**, 398; **II**, 61, 229; **III**, 426.

16-40 Darzens Glycidic Ester Condensation

(2 + 1)*OC*,*CC-cyclo*-α-Alkoxycarbonylmethylene-addition



Aldehydes and ketones condense with α-halo esters in the presence of bases to give α,β-epoxy esters, called *glycidic esters*. This is called *the Darzens condensation*.[1212] The reaction consists of an initial Knoevenagel-type reaction (**16-38**), followed by an internal S_N2 reaction (**10-9**):[1213]



Although the intermediate halo alkoxide is generally not isolated,[1214] it has been done, not only with α-fluoro esters (since fluorine is such a poor leaving group in nucleophilic substitutions), but also with α-chloro esters.[1215] This is only one of several types of evidence that rule out a carbene intermediate.[1216] Sodium ethoxide is often used as the base, though other bases, including sodium amide, are sometimes used. Aromatic aldehydes and ketones give good yields, but aliphatic aldehydes react poorly. However, the reaction can be made to give good yields

[1216]Another, based on the stereochemistry of the products, is described by Zimmerman, H.E.; Ahramjian, L. *J. Am. Chem. Soc.* ***1960***, *82*, 5459.

($\sim$80%) with simple aliphatic aldehydes, as well as with aromatic aldehydes and ketones by treatment of the α-halo ester with the base lithium bis(trimethylsilyl) amide, $LiN(SiMe_3)_2$, in THF at −78°C (to form the conjugate base of the ester) and addition of the aldehyde or ketone to this solution.[1217] If a preformed dianion of an α-halo carboxylic acid $Cl-\overset{\ominus}{C}R-COO^{\ominus}$ is used instead, α,β-epoxy acids are produced directly.[1218] The Darzens reaction has also been carried out on α-halo ketones, α-halo nitriles,[1219] α-halo sulfoxides[1220] and sulfones,[1221] α-halo *N,N*-disubstituted amides,[1222] α-halo ketimines,[1223] and even on allylic[1224] and benzylic halides. Phase-transfer catalysis has been used.[1225] Note that the reaction of a β-bromo-α-oxo ester and a Grignard reagent leads to the glycidic ester.[1226] Acid-catalyzed Darzens reactions have also been reported.[1227] (see also, **16-46**).

The Darzens reaction has been performed enantioselectively, by coupling optically active α-bromo-β-hydroxy esters with aldehydes.[1228] Chiral phase-transfer agents have been used to give epoxy ketones with modest enantioselectivity.[1229] Chiral additives have proven to be effective.[1230]

Glycidic esters can easily be converted to aldehydes (**12-40**). The reaction has been extended to the formation of analogous aziridines by treatment of an imine with an α-halo ester or an α-halo *N,N*-disubstituted amide and *t*-BuOK in the solvent 1,2-dimethoxyethane.[1231] However, yields were not high.

In the *Peterson alkenylation reaction*[1232, 1233] the lithio (or sometimes magnesio) derivative of a trialkylsilane adds to an aldehyde or ketone to give a β-hydroxysilane, which spontaneously eliminates water, or can be made to do so by treatment with acid or base, to produce an alkene. This reaction is still another alternative to the Wittig reaction (**16-44**), and is sometimes called the *silyl-Wittig reaction.*[1234] The R group can also be a COOR group, in which case the product is an α,β-unsaturated ester,[1235] or an SO_2Ph group, in which case the product is a vinylic sulfone.[1236] The stereochemistry of the product can often be controlled by whether an acid or a base is used to achieve elimination. The role of Si—O interactions has also been examined.[1237] Use of a base generally gives syn elimination (E^i mechanism, see p. 1507), while an acid usually results in anti elimination (E2 mechanism, see p. 1478).[1238] Samarium(II) iodide in HMPA has also been used for elimination of the hydroxy sulfone.[1239] α-Alkoxy benzotriazoyl sulfones ($ROCH_2SO_2Bt$, where Bt = benzothiazole, reacts with lithium hexamethyldisilazide and an aldehyde to give a vinyl ether.[1240]

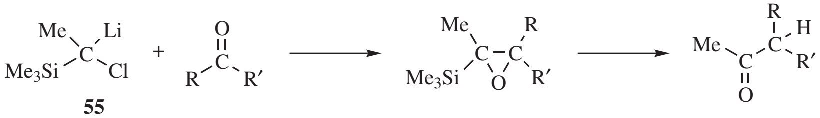
When aldehydes or ketones are treated with reagents of the form **55**, the product is an epoxy silane (**16-46**), which can be hydrolyzed to a methyl ketone.[1241] For aldehydes, this is a method for converting RCHO to a methyl ketone RCH_2COMe.



55

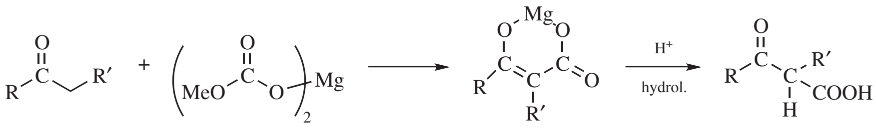
The reagents $Me_3SiCHRM$ (M = Li or Mg) are often prepared from $Me_3SiCHRCl$[1242] (by **12-38** or **12-39**), but they have also been made by **12-22** and by other procedures.[1243]

A new version of the reaction has been developed, reacting $Me_3SiCH_2CO_2Et$ with an aldehyde and a catalytic amount of CsF in DMSO.[1244] A seleno-amide derivative has been used in a similar manner.[1245]

There are no references in *Organic Syntheses*, but see OS **VIII**, 602, for a related reaction.

16-42 The Addition of Active Hydrogen Compounds to CO_2 and CS_2

α-Acylalkyl-de-methoxy-substitution (Overall reaction)



56 **57**

Ketones of the form $RCOCH_3$ and $RCOCH_2R'$ can be carboxylated indirectly by treatment with magnesium methyl carbonate **56**.[1246] Because formation of the chelate **57** provides the driving force of the reaction, carboxylation cannot be achieved at a disubstituted α position. The reaction has also been performed on CH_3NO_2 and compounds of the form RCH_2NO_2[1247] and on certain lactones.[1248] Direct carboxylation has been reported in a number of instances. Ketones have

[1248]Martin, J.; Watts, P.C.; Johnson, F. *Chem. Commun.* ***1970***, 27.

been carboxylated in the α position to give β-keto acids.[1249] The base here was lithium 4-methyl-2,16-di-*tert*-butylphenoxide.

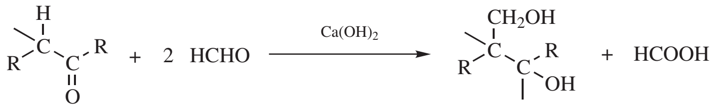
Ketones $RCOCH_2R'$ (as well as other active hydrogen compounds) undergo base-catalyzed addition to CS_2[1250] to give a dianion intermediate $RCOC^{-}R'CSS^{2-}$, which can be dialkylated with a halide R^2X to produce α-dithiomethylene ketones, $RCOCR'{=}C(SR^2)_2$.[1251] Compounds of the form ZCH_2Z' also react with bases and CS_2 to give analogous dianions.[1252]

Although reactions with N=O derivatives do not formally fall into this category of reactions, it is somewhat related. Nitroso compounds react with activated nitriles in the presence of LiBr and microwave irradiation to give a cyano imine, ArN=C(CN)Ar.[1253] This transformation has been called the *Ehrlich–Sachs reaction.*[1254]

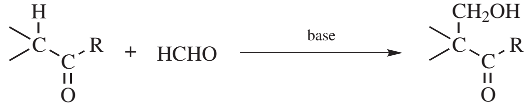
OS **VII**, 476. See also, OS **VIII**, 578.

16-43 Tollens' Reaction

***O*-Hydro-*C*(β-hydroxyalkyl)-addition**



In the *Tollens' reaction* an aldehyde or ketone containing an α hydrogen is treated with formaldehyde in the presence of $Ca(OH)_2$ or a similar base. The first step is a mixed aldol reaction (**16-34**).



The reaction can be stopped at this point, but more often a second equivalent of formaldehyde is permitted to reduce the newly formed aldol to a 1,3-diol, in a crossed Cannizzaro reaction (**19-81**). If the aldehyde or ketone has several α hydrogens, they can all be replaced. An important use of the reaction is to prepare pentaerythritol from acetaldehyde:

$$CH_3CHO \quad + \quad 4\,HCHO \longrightarrow C(CH_2OH)_4 \quad + \quad HCOOH$$

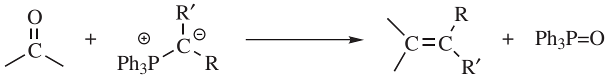
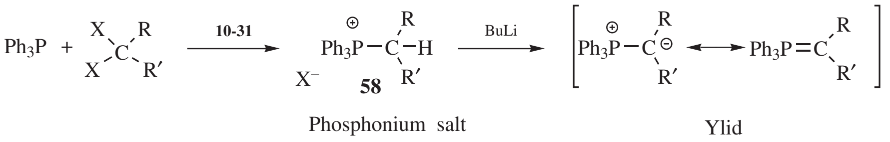
16-44 The Wittig Reaction

Alkylidene-de-oxo-bisubstitution



In the *Wittig reaction* an aldehyde or ketone is treated with a *phosphorus ylid* (also spelled ylide and called a *phosphorane*) to give an alkene.[1255] The conversion of a carbonyl compound to an alkene with a phosphorus ylid is called the *Wittig reaction*. Phosphorus ylids are usually prepared by treatment of a phosphonium salt with a base,[1256] and phosphonium salts are usually prepared from a triaryl phosphine and an alkyl halide (**10-31**):



The reaction of triphenylphosphine and an alkyl halides is facilitated by the use of microwave irradiation.[1257] Indeed, the Wittig reaction itself is assisted by microwave irradiation.[1258] Phosphonium salts are also prepared by addition of phosphines to Michael alkenes (like **15-8**) and in other ways. The phosphonium salts are most often converted to the ylids by treatment with a strong base such as

[1255]For a general treatise, see Cadogan, J.I.G. *Organophosphorus Reagents in Organic Synthesis*, Academic Press, NY, ***1979***. [1256]When phosphonium *fluorides* are used, no base is necessary, as these react directly with the substrate to give the alkene: Schiemenz, G.P.; Becker, J.; Stöckigt, J. *Chem. Ber.* ***1970***, *103*, 2077.

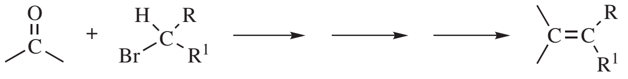
[1257]Kiddle, J.J. *Tetrahedron Lett.* ***2000***, *41*, 1339.

[1258]Frattini, S.; Quai, M.; Cereda, E. *Tetrahedron Lett.* ***2001***, *42*, 6827.; Wu, J.; Wu, H.; Wei, S.; Dai, W.-M. *Tetrahedron Lett.* ***2004***, *45*, 4401.

butyllithium, sodium amide,[1259] sodium hydride, or a sodium alkoxide, though weaker bases can be used if the salt is acidic enough. Unusual bases such as 1,5,7-triazabicyclo [4.4.0]dec-5-ene have been used to promote the Wittig reaction.[1260] In some cases, and excess of fluoride ion is sufficient.[1261] For $(Ph_3P^+)_2CH_2$, sodium carbonate is a strong enough base.[1262] When the base used does not contain lithium, the ylid is said to be prepared under "salt-free" conditions[1263] because the lithium halide (where the halide counterion comes from the phosphonium salt) is absent.

When the phosphorus ylid reacts with the aldehyde or ketone to form an alkene, a phosphine oxide is also formed. When triphenylphosphine is used to give $Ph_3P{=}CRR'$, for example, the by-product is triphenylphosphine oxide, Ph_3PO, which is sometimes difficult to separate from the other reaction products. Ylids are usually prepared from triphenylphosphine, but other triarylphosphines,[1264] trialkylphosphines,[1265] and triphenylarsine[1266] have also been used. Tellurium ylids have been prepared *in situ* from α-halo esters and $BrTeBu_2OTeBu_2Br$ and react with aldehydes to give conjugated esters.[1267] Polymer-bound aryldiphenylphosphino compounds[1268] have been used in reactions with alkyl halides to complete a Wittig reaction. Phosphines that have an α-hydrogen should be avoided, so that reaction with the chosen alkyl halide will lead to a phosphonium salt (**58**) with the α-proton at the desired position. This limitation is essential if a specific ylid is to be formed from the alkyl halide precursor. The Wittig reaction has been carried out with polymer-supported ylids.[1269] It has also been done on silica gel.[1270]

If we view the Wittig reaction from an alkyl halide starting material (alkyl halide phosphonium salt → phosphorus ylid → alkene), the halogen-bearing carbon of an alkyl halide must contain at least one hydrogen as in **59** (for deprotonation at the phosphonium salt stage).



59

[1266]An arsenic ylid has been used in a catalytic version of the Wittig reaction; that is, the R_3AsO product is constantly regenerated to produce more arsenic ylid: Shi, L.; Wang, W.; Wang, Y.; Huang, Y. *J. Org. Chem.* ***1989***, *54*, 2027; Huang, Z.-Z.; Huang, X.; Huang, Y.-Z. *Tetrahedron Lett.* ***1995***, *36*, 425.

[1267]Huang, Z.-Z.; Tang, Y. *J. Org. Chem.* ***2002***, *67*, 5320.

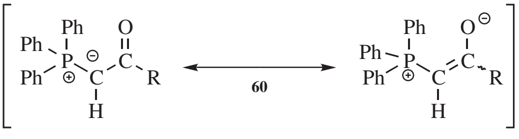
[1268]Betancort, J.M.; Barbas III, C.F. *Org. Lett.* ***2001***, *3*, 3737.

[1269]Bernard, M.; Ford, W.T.; Nelson, E.C. *J. Org. Chem.* ***1983***, *48*, 3164.

[1270]Patil, V.J.; Mävers, U. *Tetrahedron Lett.* ***1996***, *37*, 1281.

The reaction is very general.[1271] The aldehyde or ketone may be aliphatic, alicyclic, or aromatic (including diaryl ketones). Wittig reactions in which the ylid and/or the carbonyl substrate contain double or triple bonds; it may contain various functional groups, such as OH, OR, NR_2, aromatic nitro or halo, acetal, amide,[1272] or even ester groups.[1273] Note, however, that a Wittig reaction has been reported in which the carbonyl group of an ester was converted to a vinyl ether.[1274] An important advantage of the Wittig reaction is that the *position* of the new double bond is always certain, in contrast to the result in most of the base-catalyzed condensations (**16-34–16-43**). Ylids have been shown to react with lactones, however, to form ω-alkenyl alcohols.[1275] β-Lactams have also been converted to alkenyl-azetidine derivatives using phosphorus ylids.[1276] Double or triple bonds *conjugated* with the carbonyl also do not interfere, the attack being at the C=O carbon. The carbonyl partner can be generated *in situ*, in the presence of an ylid; the reaction of an alcohol with a mixture of an oxidizing agent and an ylid generates an alkene. Oxidizing agents used in this manner include $BaMnO_4$,[1277] MnO_2,[1278] and $PhI(OAc)_2$.[1279] Polyhalomethanes, such as CBr_3F, react with triphenylphosphine in the presence of diethylzinc and an aldehyde or ketone to give the *gem*-dihaloalkene, RCH(R′)=CF(Br).[1280]

The phosphorus ylid may also contain double or triple bonds and certain functional groups. Simple ylids (R, R′ = hydrogen or alkyl) are highly reactive, reacting with oxygen, water, hydrohalic acids, and alcohols, as well as carbonyl compounds and carboxylic esters, so the reaction must be run under conditions where these materials are absent. When an electron-withdrawing group, for example, COR, CN, COOR, CHO, is present in the α position, the ylids are much more stable, because the charge on the carbon is delocalized by resonance as in **60**.



60

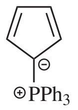
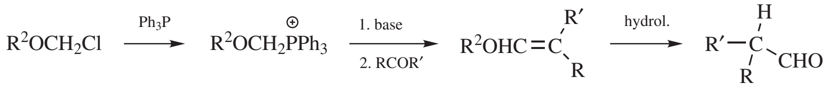
Such ylids react readily with aldehydes, but slowly or not at all with ketones.[1281] In extreme cases (e.g., **61**), the



61

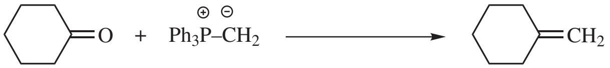
ylid does not react with ketones *or* aldehydes. Besides these groups, the ylid may contain one or two α halogens[1282] or an α OR or OAr group. In the latter case, the product is an enol ether, which can be hydrolyzed



(**10-6**) to an aldehyde,[1283] so that this reaction is a means of achieving the conversion RCOR′ → RR′CHCHO.[1284] However, the ylid may not contain an α nitro group. If the phosphonium salt contains a potential leaving group, such as Br or OMe, in the β position, treatment with a base gives elimination, instead of the ylid:

$$Ph_3\overset{\oplus}{P}CH_2CH_2Br \xrightarrow{\text{base}} Ph_3\overset{\oplus}{P}CH{=}CH_2$$

However, a β COO^- group may be present, and the product is a β,γ-unsaturated acid:[1285] This is the only convenient way to make these compounds, since elimination by any other route gives the thermodynamically more stable α,β-unsaturated isomers. This is an illustration of the utility of the Wittig method for the specific location of a double bond. Another illustration is the conversion of cyclohexanones to alkenes containing exocyclic double bonds, for example,[1286]



[1281]For successful reactions of stabilized ylids with ketones, under high pressure, see Isaacs, N.S.; El-Din, G.N. *Tetrahedron Lett.* ***1987***, *28*, 2191. See also, Dauben, W.G.; Takasugi, J.J. *Tetrahedron Lett.* ***1987***, *28*, 4377.

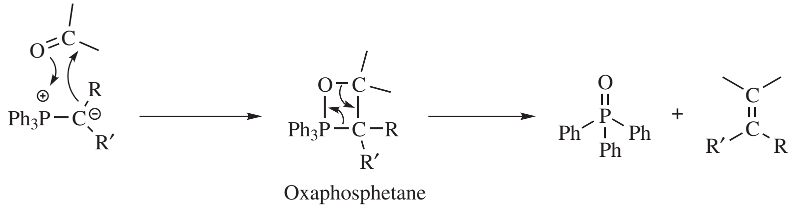
[1286]Wittig, G.; Schöllkopf, U. *Chem. Ber.* ***1954***, *87*, 1318.

Still another example is the easy formation of anti-Bredt bicycloalkenones[1287] (see p. 229). As indicated above, α,α′-dihalophosphoranes can be used to prepare 1,1-dihaloalkenes. Another way to prepare such compounds[1288] is to treat the carbonyl compound with a mixture of CX_4 (X = Cl, Br, or I) and triphenylphosphine, either with or without the addition of zinc dust (which allows less Ph_3P to be used).[1289] Aryl aldehydes react with these dihalophosphoranes to give aryl alkynes after treatment of the initially formed vinyl halide with potassium *tert*-butoxide.[1290] Formamides have been converted to ynamines by reaction with a mixture of PPh_3/CCl_4 followed by *n*-butyllithium.[1291] The carbonyl compound can be generated *in situ*, in the presence of the phosphorane. A cyclopropylcarbonyl alcohol was converted to a β-cyclopropyl-α,β-unsaturated ester by reaction with MnO_2 in the presence of $Ph_3P{=}CHCO_2Me$.[1292]

The mechanism[1293] of the key step of the Wittig reaction is as follows:[1294]



The energetics of ylid formation and their reaction is solution has been studied.[1295] For many years it was assumed that a diionic compound, called a *betaine*, is an intermediate on the pathway from the starting compounds

[1287]Bestmann, H.J.; Schade, G. *Tetrahedron Lett.* ***1982***, *23*, 3543.

[1288]For a list of references to the preparation of haloalkenes by Wittig reactions, with references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, ***1999***, pp. 725–727.

[1289]See, for example, Rabinowitz, R.; Marcus, R. *J. Am. Chem. Soc.* ***1962***, *84*, 1312; Ramirez, F.; Desai, N.B.; McKelvie, N. *J. Am. Chem. Soc.* ***1962***, *84*, 1745; Corey, E.J.; Fuchs, P.L. *Tetrahedron Lett.* ***1972***, 3769; Posner, G.H.; Loomis, G.L.; Sawaya, H.S. *Tetrahedron Lett.* ***1975***, 1373; Suda, M.; Fukushima, A. *Tetrahedron Lett.* ***1981***, *22*, 759; Gaviña, F.; Luis, S.V.; Ferrer, P.; Costero, A.M.; Marco, J.A. *J. [1292]Blackburn, L.; Wei, X.; Taylor, R.J.K. *Chem. Commun.* ***1999***, 1337.

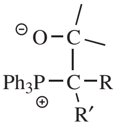
[1293]For a review of the mechanism, see Cockerill, A.F.; Harrison, R.G., in Patai, S. *The Chemistry of Functional Groups: Supplement A*, pt. 1, Wiley, NY, ***1977***, pp. 232–240. For a thorough discussion, see Vedejs, E.; Marth, C.F. *J. Am. Chem. Soc.* ***1988***, *110*, 3948.

[1294]It has been contended that another mechanism, involving single electron transfer, may be taking place in some cases: Olah, G.A.; Krishnamurthy, V.V. *J. Am. Chem. Soc.* ***1982***, *104*, 3987; Yamataka, H.; Nagareda, K.; Hanafusa, T.; Nagase, S. *Tetrahedron Lett.* ***1989***, *30*, 7187. A diradical mechanism has also been proposed for certain cases: Ward, Jr., W.J.; McEwen, W.E. *J. Org. Chem.* ***1990***, *55*, 493.

[1295]Arnett, E.M.; Wernett, P.C. *J. Org. Chem.* ***1993***, *58*, 301.

to the oxaphosphetane, and in fact it may be so, but there is little evidence for it.[1296]



Betaine

"Betaine" precipitates have been isolated in certain Wittig reactions,[1297] but these are betaine–lithium halide adducts, and might just as well have been formed from the oxaphosphetane as from a true betaine.[1298] However, there is one report of an observed betaine lithium salt during the course of a Wittig reaction.[1299] An X-ray structure was determined for a gauche betaine from a thio-Wittig reaction.[1300] In contrast, there is much evidence for the presence of the oxaphosphetane intermediates, at least with unstable ylids. For example, ^{31}P NMR spectra taken of the reaction mixtures at low temperatures[1301] are compatible with an oxaphosphetane structure that persists for some time but not with a tetra-coordinated phosphorus species. Since a betaine, an ylid, and a phosphine oxide all have tetracoordinated phosphorus, these species could not be causing the spectra, leading to the conclusion that an oxaphosphetane intermediate is present in the solution. In certain cases oxaphosphetanes have been isolated.[1302] It has even been possible to detect cis and trans isomers of the intermediate oxaphosphetanes by NMR spectroscopy.[1303] According to this mechanism, an optically active phosphonium salt $RR'R^2P^+CHR^2$ should retain its configuration all the way through the reaction, and it should be preserved in the phosphine oxide $RR'R^2PO$. This has been shown to be the case.[1304]

The proposed betaine intermediates can be formed, in a completely different manner, by nucleophilic substitution by a phosphine on an epoxide (**10-35**):

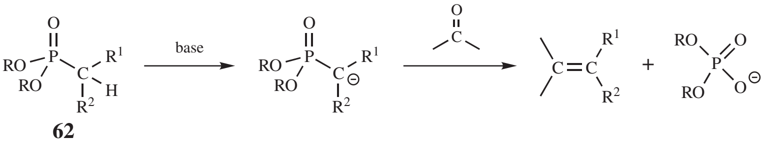
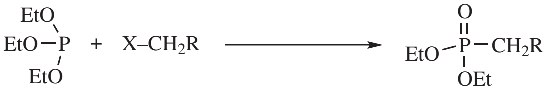
Betaines formed in this way can then be converted to the alkene, and this is one reason why betaine intermediates were long accepted in the Wittig reaction.

The Wittig reaction has also been carried out with phosphorus ylids other than phosphoranes, the most important being prepared from phosphonates, such as **62**.[1305]



This method, sometimes called the *Horner–Emmons*, *Wadsworth–Emmons*, or *Wittig–Horner reaction*,[1306] has several advantages over the use of phosphoranes, including selectivity.[1307] These ylids are more reactive than the corresponding phosphoranes, and when R^1 or R^2 is an electron-withdrawing group, these compounds often react with ketones that are inert to phosphoranes. High pressure has been used to facilitate this reaction.[1308] In addition, the phosphorus product is a phosphate ester and hence soluble in water, unlike Ph_3PO, which makes it easy to separate it from the alkene product. Phosphonates are also cheaper than phosphonium salts and can easily be prepared by the *Arbuzov reaction*:[1309]



Phosphonates have also been prepared from alcohols and $(ArO)_2P(=O)Cl$, NEt_3 and a $TiCl_4$ catalyst.[1310] The reaction of $(RO)_2P(=O)H$ and aryl iodides with a CuI catalyst leads to aryl phosphonates.[1311] Polymer-bound phosphonate esters have been used for olefination.[1312] Dienes are produced when allylic phosphonate esters react with aldehydes.[1313]

Stereoselective alkenylation reactions have been achieved using chiral additives[1314] or auxiliaries.[1315] Ylids formed from phosphine oxides,

$$\underset{\displaystyle \overset{\|}{O}}{Ar_2P}-CHRR'$$

phosphonic acid bisamides, $(R^2_2N)_2POCHRR'$,[1316] and alkyl phosphonothionates, $(MeO)_2PSCHRR'$,[1317] share some of these advantages. Reagents, such as $Ph_2POCH_2NR'_2$, react with aldehydes or ketones (R_2COR^3) to give good yields of enamines ($R^2R^3C{=}CHNR$).[1318] (*Z*)-Selective reagents are also known,[1319] including the use of a di(2,2,2-trifluoroethoxy)phosphonate with KHMDS and 18-crown-6.[1320] An interesting intramolecular version of the Horner–Emmons reaction leads to alkynes.[1321] The reaction of a functionalized aldehyde (R—CHO) with $(MeO)_2POCHN_2$, leads to the alkyne ($R{-}C{\equiv}CH$).[1322]

Some Wittig reactions give the (*Z*)-alkene; some the (*E*), and others give mixtures, and the question of which factors determine the stereoselectivity has been much studied.[1323] It is generally found that ylids containing stabilizing groups or formed from trialkylphosphines give (*E*)-alkenes. However, ylids formed from triarylphosphines and not containing stabilizing groups often give (*Z*) or a mixture of (*Z*) and (*E*)-alkenes.[1324] One explanation for this[1193] is that the reaction of the ylid with the carbonyl compound is a [2 + 2]-cycloaddition, which in order to be concerted must adopt the $[_{\pi}2_s + _{\pi}2_a]$ pathway. As we have seen earlier (p. 1225), this pathway leads to the formation of the more sterically crowded product, in this case the *Z* alkene. If this explanation is correct, it is not easy to explain the predominant formation of (*E*)

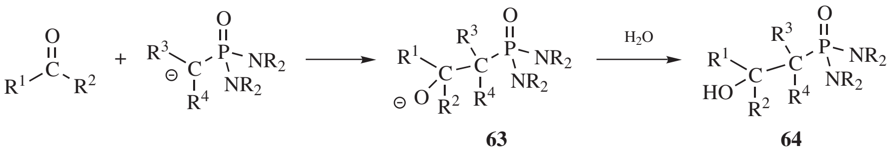
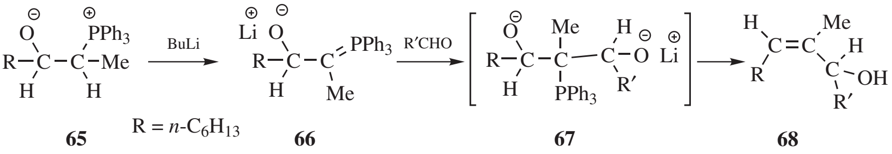
products from stable ylids, but (*E*) compounds are of course generally thermodynamically more stable than the (*Z*) isomers, and the stereochemistry seems to depend on many factors.



The (*E/Z*) ratio of the product can often be changed by a change in solvent or by the addition of salts.[1325] Another way of controlling the stereochemistry of the product is by use of the aforementioned phosphonic acid bisamides. In this case, the betaine (**63**) does form and when treated with water gives the β-hydroxyphosphonic acid bisamides **64**, which can be crystallized and then cleaved to $R^1R^2C{=}CR^3R^4$ by refluxing in benzene or toluene in the presence of silica gel.[1316] **64** are generally formed as mixtures of diastereomers, and these mixtures can be separated by recrystallization. Cleavage of the two diastereomers gives the two isomeric alkenes. Optically active phosphonic acid bisamides have been used to give optically active alkenes.[1326] Another method of controlling the stereochemistry of the alkene [to obtain either the (*Z*) or (*E*) isomer] starting with a phosphine oxide (Ph_2POCH_2R), has been reported.[1327]



In reactions where the betaine–lithium halide intermediate is present, it is possible to extend the chain further if a hydrogen is present α to the phosphorus. For example, reaction of ethylidnetriphenylphosphorane with heptanal at −78°C gave **65**, which with butyllithium gave the ylid **66**. Treatment of this with an aldehyde R′CHO gave the intermediate **67**, which after workup gave **68**.[1328] This reaction gives the unsaturated alcohols **68** stereoselectively. **66** also reacts with other electrophiles. For example, treatment of **66** with *n*-chlorosuccinimide or $PhICl_2$ gives the vinylic chloride RCH=CMeCl stereoselectively: NCS giving the cis and $PhICl_2$

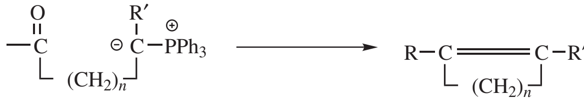
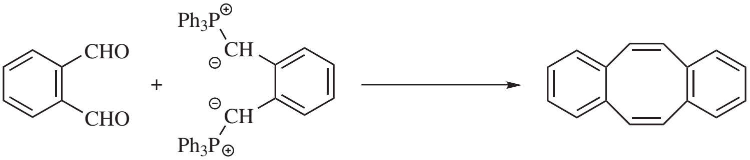
the trans isomer.[1329] The use of Br_2 and $FClO_3$ (see **12-4** for the explosive nature of this reagent) gives the corresponding bromides and fluorides, respectively.[1330] Reactions of **66** with electrophiles have been called *scoopy* reactions (α *s*ubstitution plus *c*arbonyl alkeneylation via β-*o*xido *p*hosphorus *ylid*s).[1331]

The reaction of a phosphonate ester, DBU, NaI, and HMPA with an aldehyde leads to a conjugated ester with excellent (*Z*)-selectivity.[1332] A (*Z*)-selective reaction was reported using a trifluoroethyl phosphonate in a reaction with an aldehyde and potassium *tert*-butoxide.[1333]

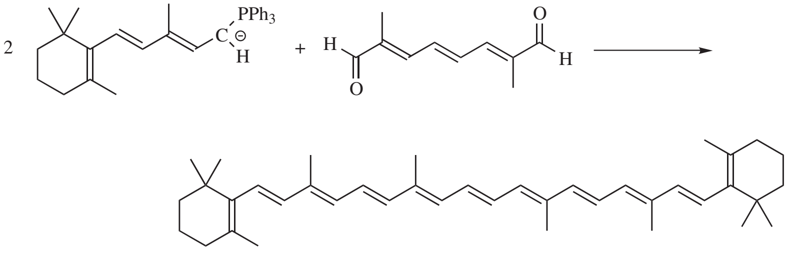
The Wittig reaction has been carried out intramolecularly, to prepare rings containing from 5 to 16 carbons,[1334] both by single ring closure



and double ring closure.[1335]



The Wittig reaction has proved very useful in the synthesis of natural products, some of which are quite difficult to prepare in other ways.[1336] One example out of many is the synthesis of β-carotene:[1337]



β-Carotene

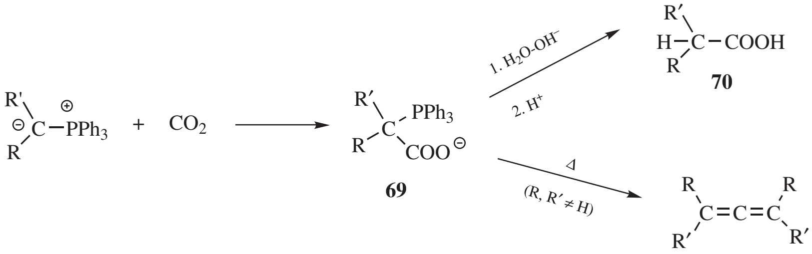
RR′CHX → RR′CHCOOH) or (if neither R nor R′ is hydrogen) dimerized to allenes.



Although phosphorus ylids are most commonly used to alkenylation reactions, nitrogen ylids can occasionally be used. As an example, the reaction of *N*-benzyl-*N*-phenylpiperidinium bromide with base generated a N-ylid, which reacted with benzaldehyde to form styrene.[1345] The structure has been determined for an intermediate in an aza-Wittig reaction.[1346]

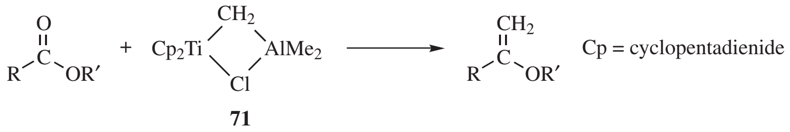
16-45 Tebbe, Petasis and Alternative Alkenylations

Methylene-de-oxo-bisubstitution



A useful alternative to phosphorus ylids are the titanium reagents, such as, **71**, prepared from dicyclopentadienyltitanium dichloride and trimethylaluminum.[1347] Treatment of a carbonyl compound with the titanium cyclopentadienide complex **71** (*Tebbe's reagent*) in toluene–THF containing a small amount of pyridine[1348] leads to the alkene. Dimethyltitanocene (Me_2TiCp_2), called the *Petasis reagent*, is a convenient and highly useful alternative to **71**.[1349] The mechanism of Petasis olefination has been examined.[1350] Tebbe's reagent and the Petasis reagent give good results with ketones.[1351] An important feature of these new reagents is that

carboxylic esters and lactones[1352] can be converted in good yields to the corresponding enol ethers. The enol ether can be hydrolyzed to a ketone (**10-6**), so this is also an indirect method for making the conversion RCOOR′ → $RCOCH_3$ (see also, **16-82**). Conjugated esters are converted to alkoxy-dienes with this reagent.[1353] Lactams, including β-lactams, are converted with alkylidene cycloamines (alkylidene azetidines from β-lactams, which are easily hydrolyzed to β-amino ketones).[1354]

Besides stability and ease of preparation, another advantage of the Petasis reagent is that structural analogs can be prepared, including $Cp_2Ti(C_3H_5)_2$[1355] (C_3H_5 = cyclopropyl), $CpTi(CH_2SiMe_3)_3$,[1356] and $Cp_2TiMe(CH{=}CH_2)$.[1357] In another variation, 2 equivalents of $Cp_2Ti[P(OEt)_3]_2$ reacted with a ketone in the presence of 1,1-diphenylthiocyclobutane to give the alkenylcyclobutane derivative.[1358] An alternative titanium reagent was prepared using $TiCl_4$, magnesium metal and dichloromethane, reacting with both ketones[1359] and esters[1360] to give alkenes or vinyl ethers, respectively. Alkenes are generated form ketones and alkyl iodides in the presence of a catalytic amount of $Cp_2Ti[POEt)_3]_2$.[1361]

α,α-Dibromosulfones ($ArSO_2SHBr_2$) react with ketones in the presence of Sm/SmI_2 and a $CrCl_3$ catalyst gives to corresponding vinyl sulfone.[1362] Imides are converted to alkylidene lactams when treated with an alkyl halide, 2.5 equivalents of SmI_2 and a NiI_2 catalyst.[1363]

Carboxylic esters undergo the conversion C=O → C=CHR (R = primary or secondary alkyl) when treated with $RCHBr_2$, Zn,[1364] and $TiCl_4$ in the presence of *N,N,N′,N′*-tetramethylethylenediamine.[1365] Metal carbene complexes[1366] $R_2C = ML_n$ (L = ligand), where M is a transition metal, such as Zr, W, or Ta, have also been

used to convert the C=O of carboxylic esters and lactones to CR_2.[1367] It is likely that the complex $Cp_2Ti=CH_2$ is an intermediate in the reaction with Tebbe's reagent.

There are a few other methods for converting ketones or aldehydes to alkenes. When a ketone is treated with $CH_3CHBr_2/Sm/SmI_2$, with a catalytic amount of $CrCl_3$, for example, the alkene is formed.[1368] α-Halo esters also react with $CrCl_2$ in the presence of a ketone to give vinyl halides.[1369] In another reaction, an aldehydes reacted with EtCHBr(OAc) in the presence of $Zn/CrCl_3$ to give the alkene.[1370] α-Diazo esters react with ketones in the presence of an iron catalyst to give the corresponding alkene.[1371] α-Diazo silylalkanes react similarly in the presence of a rhodium catalyst.[1372] Benzylic alcohols also react with α-diazo silylalknes in the presence of a rhodium catalyst, to give alkenes after pretreatment with oxygen and a palladium catalyst.[1373] The react of aryl aldehydes and $MeC(CO_2Et)_3$ with a catalytic amount of phenol leads to the corresponding conjugated ethyl ester ($ArCH=CHCO_2Et$).[1374]

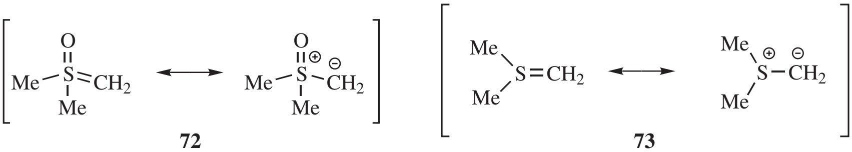
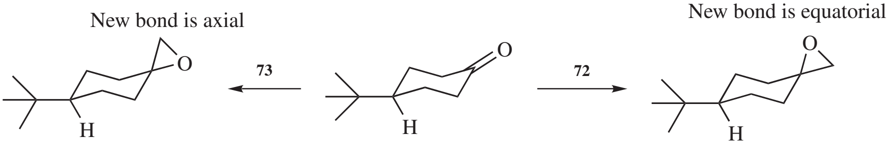
methylid (**73**).[1376] For most purposes, **72** is the



72 **73**

reagent of choice, because **73** is much less stable and ordinarily must be used as soon as it is formed, while **72** can be stored several days at room temperature. When diastereomeric epoxides can be formed, **73** usually attacks from the more hindered and **72** from the less-hindered side. Thus, 4-*tert*-butylcyclohexanone, treated with **72** gave exclusively **75** while **73** gave mostly **74**.[1377] Another difference in behavior between the



74 **75**

two reagents is that with α,β-unsaturated ketones, **72** gives only cyclopropanes (reaction **15-64**), while **73** gives oxirane formation. Other sulfur ylids have been used in an analogous manner, to transfer CHR or CR_2.[1378] High yields have been achieved by the use of sulfonium ylids anchored to insoluble polymers under phase-transfer conditions.[1379] A solvent-free version of this reaction has been developed using powdered K *tert*-butoxide and $Me_3S^+I^-$.[1380] Note that treatment of epoxides with 2 equivalents of $Me_2S{=}CH_2$ leads to allylic alcohols.[1381] Other sulfur ylids convert aldehydes to epoxides, including the one generated *in situ* from $RR'S^+CH_2COO^-$.[1382] Chiral sulfur ylids[1383] have been prepared, giving

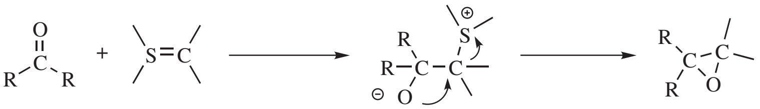
the epoxide with good asymmetric induction.[1384] Chiral selenium ylids have been used in a similar manner.[1385]

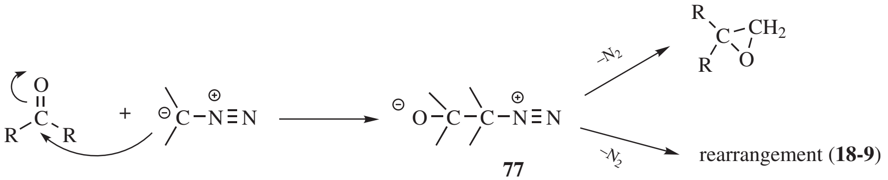


76

The generally accepted mechanism for the reaction between sulfur ylids and aldehydes or ketone is formation of **76**, with displacement of the Me_2S leaving group by the alkoxide.[1386] This mechanism is similar to that of the reaction of sulfur ylids with C=C double bonds (**15-64**).[1387] The stereochemical difference in the behavior of **72** and **73** has been attributed to formation of the betaine **76** being reversible for **72**, but not for the less stable **73**, so that the more-hindered product is the result of kinetic control and the less-hindered of thermodynamic control.[1388]

Phosphorus ylids do not give this reaction, but give **16-44** instead.

Aldehydes and ketones can also be converted to epoxides by treatment with a diazoalkane,[1389] most commonly diazomethane, but an important side reaction is the formation of an aldehyde or ketone with one more carbon than the starting compound (reaction **18-9**). The reaction can be carried out with many aldehydes, ketones, and quinones, usually with a rhodium catalyst.[1390] A mechanism that accounts for both products is



77

Compound **77** or nitrogen-containing derivatives of it have sometimes been isolated.

An alternative route to epoxides from ketones uses α-chloro sulfones and potassium *tert*-butoxide to give α,β-epoxy sulfones.[1391] A similar reaction was reported

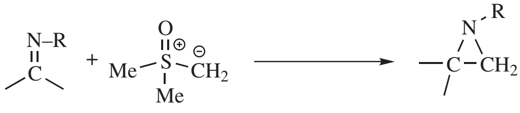
using KOH and 10% of a chiral phase-transfer agent, giving moderate enantioselectivity in the epoxy sulfone product.[1392]

Dihalocarbenes and carbenoids, which readily add to C=C bonds (**15-64**), do not generally add to the C=O bonds of ordinary aldehydes and ketones.[1393] See also, **16-91**.

OS **V**, 358, 755.

16-47 The Formation of Aziridines from Imines

(1 + 2)*NC*,*CC*-*cyclo*-Methylene-addition



72

Just as sulfur ylids react with the carbonyl of an aldehyde or ketone to give an epoxide, tellurium ylids react with imines to give an aziridine. The reaction of an allylic tellurium salt, $RCH{=}CHCH_2Te^+Bu_2\ Br^-$, with lithium hexamethyldisilazide in HMPA/toluene leads to the tellurium ylid via deprotonation. In the presence of an imine, the ylid add to the imine and subsequent displacement of Bu_2Te generates an aziridine with a pendant vinyl group.[1394]

16-48 The Formation of Episulfides and Episulfones[1395]

Epoxides can be converted directly to episulfides by treatment with NH_4SCN and ceric ammonium nitrate.[1396] Diazoalkanes, treated with sulfur, give episulfides.[1397] It is likely that $R_2C{=}S$ is an intermediate, which is attacked by another molecule of diazoalkane, in a process similar to that shown in **16-46**. Thioketones *do* react with diazoalkanes to give episulfides.[1398] Thioketones have also been converted to episulfides with sulfur ylids.[1377] Carbenes, such as the dichlorocarbene from $CHCl_3$ and base, react with thioketones to give an

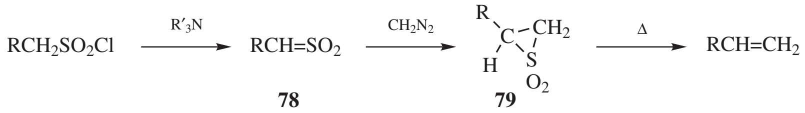
α,α-dichloro episufide.[1399]

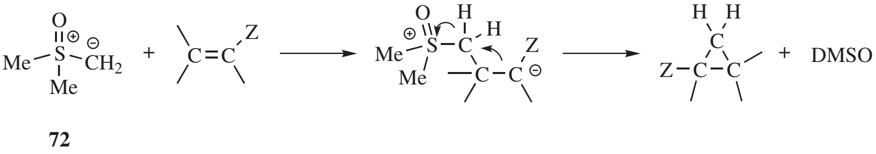


Alkanesulfonyl chlorides, when treated with diazomethane in the presence of a base (usually a tertiary amine), give episulfones (**79**).[1400] The base removes HCl from the sulfonyl halide to produce the highly reactive sulfene (**78**) (**17-14**), which then adds CH_2. The episulfone can then be heated to give off SO_2 (**17-20**), making the entire process a method for achieving the conversion $RCH_2SO_2Cl \rightarrow RCH{=}CH_2$.[1401]

OS **V**, 231, 877.

16-49 Cyclopropanation of Conjugated Carbonyl Compounds

Double-bond compounds that undergo the Michael reaction (**15-24**) can be converted to cyclopropane derivatives with sulfur ylids.[1402] Among the most common of these is dimethyloxosulfonium methylid



72,[1403] which is widely used to transfer CH_2 to activated double bonds, but other sulfur ylids

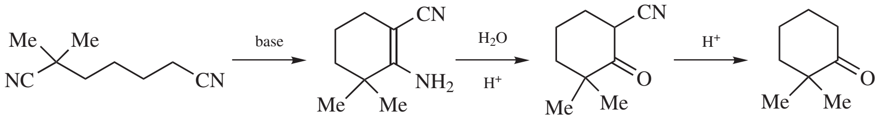
have also been used. A combination of DMSO and KOH in an ionic liquid converts conjugated ketones to α,β-cyclopropyl ketones.[1404] Both CHR and CR_2 can be added in a similar manner with certain nitrogen-containing compounds. For example, ylids,[1405] such as **80**, add various groups to activated double bonds.[1406] Sulfur ylids react with allylic alcohols in the presence of MnO_2 and molecular sieve 4 Å to give the cyclopropyl aldehyde.[1407] Similar reactions have been performed with phosphorus ylids,[1408] with pyridinium ylids,[1409] and with the compounds $(PhS)_3CLi$ and $Me_3Si(PhS)_2CLi$.[1410] The reactions with ylids such as these involve of course nucleophilic acyl addition.

Other reagents can be used to convert an aldehyde or ketone to a cyclopropane derivative. Conjugated ketones react with $Cp_2Zr(CH_2{-}CH_2)$ and PMe_3 to give a vinyl cyclopropane derivative after treatment with aqueous sulfuric acid.[1411]

16-50 The Thorpe Reaction

N-Hydro-*C*-(α-cyanoalkyl)-addition

In the *Thorpe reaction*, the α carbon of one nitrile molecule is added to the CN carbon of another, so this reaction is analogous to the aldol reaction (**16-34**). The C=NH bond is, of course, hydrolyzable (**16-2**), so β-keto nitriles can be prepared in this manner. The Thorpe reaction can be done intramolecularly, in which case it is



81

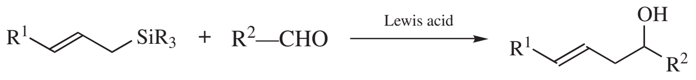
called the *Thorpe-Ziegler reaction*.[1412] This is a useful method for closing large rings. Yields are high for five- to eight-membered rings, fall off to about zero for rings of nine to thirteen members, but are high again for fourteen-membered and larger rings, if high-dilution techniques are employed. The product in the Thorpe–Ziegler reaction is not the imine, but the tautomeric enamine, for example, **81**; if desired this can be hydrolyzed to an α-cyano ketone (**16-2**), which can in turn be hydrolyzed and decarboxylated (**16-4**, **12-40**). Other active-hydrogen compounds can also be added to nitriles.[1413]

OS **VI**, 932.

H. Other Carbon or Silicon Nucleophiles

16-51 Addition of Silanes

***O*-Hydro-*C*-alkyl-addition**



Allylic silanes react with aldehydes, in the presence of Lewis acids, to give a homoallylic alcohol.[1414] In the case of benzylic silanes, this addition reaction has been induced with $Mg(ClO_4)_2$ under photochemical conditions.[1415] Cyclopropylcarbinyl silanes add to acetals in the presence of TMSOTf to give a homoallylic alcohol.[1416] Allyltrichlorosilane adds an allyl group to an aldehyde in the presence of a cyclic urea and AgOTf.[1417] The addition of chiral additives leads to the alcohol with good asymmetric induction.[1418] In a related reaction, allylic silanes react with acyl halides to produce the corresponding carbonyl derivative. The reaction of phenyl chloroformate, allyltrimethylsilane and $AlCl_3$, for example, gave phenyl but-3-enoate.[1419]

Allylic silanes also add to imines, in the presence of $TiCl_4$, to give amines.[1420]

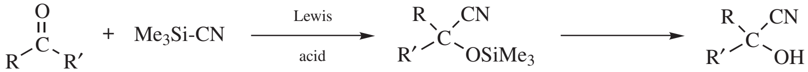
16-52 The Formation of Cyanohydrins

O-Hydro-*C*-cyano-addition

The addition of HCN to aldehydes or ketones produces cyanohydrins.[1421] This is an equilibrium reaction, and for aldehydes and aliphatic ketones the equilibrium lies to the right; therefore the reaction is quite feasible, except with sterically hindered ketones such as diisopropyl ketone. However, ketones ArCOR give poor yields, and the reaction cannot be carried out with ArCOAr since the equilibrium lies too far to the left. With aromatic aldehydes the benzoin condensation (**16-55**) competes. With α,β-unsaturated aldehydes and ketones, 1,4-addition competes (**15-38**). The reaction has been carried out enantioselectively: optically active cyanohydrins were prepared with the aid of optically active catalysts.[1422] Hydrogen cyanide adds to aldehydes in the presence of a lyase to give the cyanohydrin with good enantioselectivity.[1423] Cyanohydrins have been formed using a lyase in an ionic liquid.[1424]



82

Ketones of low reactivity, such as ArCOR, can be converted to cyanohydrins by treatment with diethylaluminum cyanide (Et_2AlCN) (see OS **VI**, 307) or, indirectly, with cyanotrimethylsilane (Me_3SiCN)[1425] in the presence of a Lewis acid or base,[1426]

followed by hydrolysis of the resulting *O*-trimethylsilyl cyanohydrin **82**. Solvent-free conditions have been reported using TMSCN, an aldehydes and potassium carbonate.[1427] Amine *N*-oxides catalyze the reaction[1428] as does tetra-butylammonium cyanide.[1429] Lithium perchlorate in ether facilitates this reaction.[1430] With $MgBr_2$ as a catalyst, the reaction proceeds to good syn selectivity. [1431] Other useful catalysts include platinum complexes,[1432] Ti(O*i*Pr)$_4$,[1433] and $InBr_3$.[1434] When $TiCl_4$ is used, the reaction between Me_3SiCN and aromatic aldehydes or ketones gives α-chloro nitriles (ClCRR′—CN).[1435] The use of chiral additives in this latter reaction leads to cyanohydrins with good asymmetric induction.[1436] Sulfoximine–titanium reagents have been used in enantioselective trimethylsilyl cyanations of aldehydes.[1437] Chiral transition-metal catalysts have been used to give *O*-trialkylsilyl cyanohydrins with good enantioselectivity, including titanium complexes[1438] as well as complexes of other metals.[1439] A vanadium catalysts has been used in an ionic liquid.[1440] Note that the reaction of an aldehyde and TMSCN in the presence of aniline and a $BiCl_3$ catalyst leads to an α-cyano amine.[1441] α-Cyano amines are also formed by the reaction of an aldehyde with $(Et_2N)_2BCN$.[1442]

Ketones can be converted to cyanohydrin *O*-carbonates, $R_2C(CN)OCO_2R'$, by reaction with EtO_2C—CN. In the presence of a Cinchona alkaloid, the product is formed with good enantioselectivity.[1443] Potassium cyanide and acetic anhydride reacts with an aldehyde in the presence of a chiral titanium catalyst to give an α-acetoxy nitrile.[1444]

Rather than direct reaction with an aldehyde or ketone, the bisulfite addition product is often treated with cyanide. The addition is nucleophilic and the actual nucleophile is $^{-}$CN, so the reaction rate is increased by the addition of base.[1445] This was demonstrated by Lapworth in 1903, and consequently this was one of the first organic mechanisms to be known.[1446] This method is especially useful for aromatic aldehydes, since it avoids competition from the benzoin condensation. If desired, it is possible to hydrolyze the cyanohydrin *in situ* to the corresponding α-hydroxy acid. This reaction is important in the *Kiliani–Fischer* method of extending the carbon chain of a sugar.

A particularly useful variation of this reaction uses cyanide rather than HCN. α-Amino nitriles[1447] can be prepared in one step by the treatment of an aldehyde or ketone with NaCN and NH_4Cl. This is called the *Strecker synthesis*;[1448] and it is a special case of the Mannich reaction (**16-19**). Since the CN is easily hydrolyzed to the acid, this is a convenient method for the preparation of α-amino acids. The reaction has also been carried out with $NH_3 + HCN$ and with NH_4CN. Salts of primary and secondary amines can be used instead of NH_4^+ to obtain *N*-substituted and *N,N*-disubstituted α-amino nitriles. Unlike **16-52**, the Strecker synthesis is useful for aromatic as well as aliphatic ketones. As in **16-52**, the Me_3SiCN method has been used; **76** is converted to the product with ammonia or an amine.[1449] The effect of pressure on the Strecker synthesis has been studied.[1450]

16-53 The Addition of HCN to C=N and C≡N Bonds

N-Hydro-*C*-cyano-addition

W=H, R, Ar, OH, NHAr, etc.

HCN adds to imines, Schiff bases, hydrazones, oximes, and similar compounds. Cyanide can be added to iminium ions to give α-cyano amines (**83**).

83

As in **16-50**, the addition to imines has been carried out enantioselectively.[1451] Chiral ammonium salts have been used with HCN.[1452] TMSCN reacts with *N*-tosyl imines in the presence of BF_3•OEt_2 to give the α-cyano *N*-tosyl amine.[1453] In the presence of a chiral zirconium[1454] or aluminum[1455] catalyst, Bu_3SnCN react with imines to give α-cyanoamines enantioselectively. The reaction of an imine and TMSCN gives the cyano amine with good enantioselectivity using a chiral scandium catalyst.[1456] Titanium catalysts have been used in the presence of a chiral Schiff base.[1457] Treatment of an imine with a chiral 1,4,6- triazabicyclo[3.3.0]oct-4-ene and then HCN give the α-cyano amine with good enantioselectivity.[1458]

The addition of KCN to triisopropylbenzenesulfonyl hydrazones **84** provides an indirect method for achieving the conversion RR′CO → RR′CHCN.[1459] The reaction is successful for hydrazones of aliphatic aldehydes and ketones.

$$\underset{\mathbf{84}}{RR'C{=}NNHSO_2Ar} + KCN \xrightarrow{MeOH} RR'CHCN \qquad Ar = 2,4,6\text{-}(i\text{-}Pr)_3C_6H_2$$

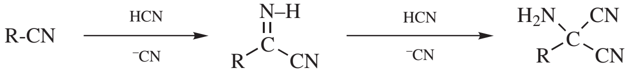
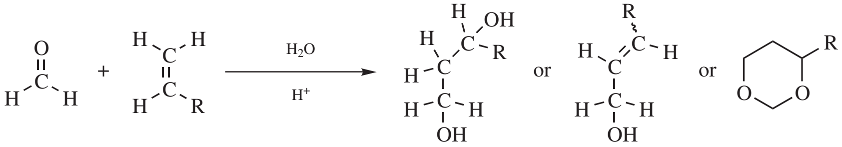
HCN can also be added to the C≡N bond to give iminonitriles or α-aminomalononitriles.[1460]

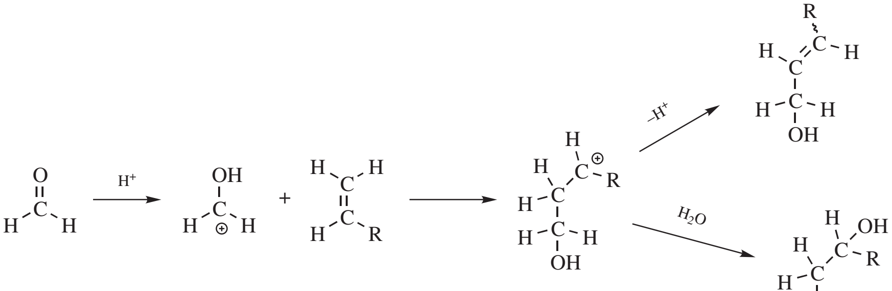


OS **V**, 344. See also, OS **V**, 269.

16-54 The Prins Reaction



The addition of an alkene to formaldehyde in the presence of an acid[1461] catalyst is called the *Prins reaction*.[1462] Three main products are possible; which one predominates depends on the alkene and the conditions. When the product is the 1,3-diol or the dioxane,[1463] the reaction involves addition to the C=C as well as to the C=O. The mechanism is one of electrophilic attack on both double bonds. The acid first protonates the C=O, and the resulting carbocation is attacked by the C=C to give **85**.



The cation product **85** can undergo loss of H^+ to give the alkene or add water to give the diol.[1464] It has been proposed that **85** is stabilized by neighboring-group

[1460]For an example, see Ferris, J.P.; Sanchez, R.A. *Org. Synth. V*, 344.

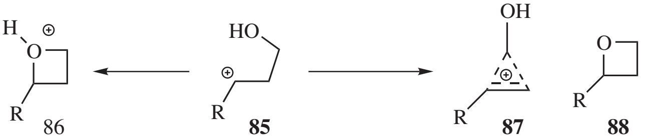
[1461]The Prins reaction has also been carried out with basic catalysts: Griengl, H.; Sieber, W. *Monatsh. Chem.* ***1973***, *104*, 1008, 1027.

[1462]For reviews, see Adams, D.R.; Bhatnagar, S.P. *Synthesis* ***1977***, 661; Isagulyants, V.I.; Khaimova, T.G.; Melikyan, V.R.; Pokrovskaya, S.V. *Russ. Chem. Rev.* ***1968***, *37*, 17. For a list of references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, ***1999***, p. 248.

[1463]The reaction to produce dioxanes has also been carried out with equimolar mixtures of formaldehyde and another aldehyde RCHO. The R appears in the dioxane on the carbon between the two oxygens: Safarov, M.G.; Nigmatullin, N.G.; Ibatullin, U.G.; Rafikov, S.R. *Doklad. Chem.* ***1977***, *236*, 507.

[1464]Hellin, M.; Davidson, M.; Coussemant, F. *Bull. Soc. Chim. Fr.* ***1966***, 1890, 3217.

attraction, with either the oxygen[1465] or a carbon[1466] stabilizing the charge (**86** and



86 **85** **87** **88**

87, respectively). This stabilization is postulated to explain the fact that with 2-butenes[1467] and with cyclohexenes the addition is anti. A backside attack of H_2O on the three- or four-membered ring would account for it. Other products are obtained too, which can be explained on the basis of **86** or **87**.[1465,1466] Additional evidence for the intermediacy of **86** is the finding that oxetanes (**88**) subjected to the reaction conditions (which would protonate **88** to give **86**) give essentially the same product ratios as the corresponding alkenes.[1468] An argument against the intermediacy of **86** and **87** is that not all alkenes show the anti-stereoselectivity mentioned above. Indeed, the stereochemical results are often quite complex, with syn, anti, and nonstereoselective addition reported, depending on the nature of the reactants and the reaction conditions.[1469] Since addition to the C=C bond is electrophilic, the reactivity of the alkene increases with alkyl substitution and Markovnikov's rule is followed. The dioxane product may arise from a reaction between the 1,3-diol and formaldehyde[1470] (**16-5**) or between **86** and formaldehyde.

Lewis acids, such as $SnCl_4$, also catalyze the reaction, in which case the species that adds to the alkenes is $H_2C^+—O^-—SnCl_4$.[1471] Montmorillonite K10 clay containing zinc (IV) has been used to promote the reaction.[1472] The reaction can also be catalyzed by peroxides, in which case the mechanism is probably a free-radical one. Other transition metal complexes can be used to form homoallylic alcohols. A typical example is the reaction of methylenecyclohexane with an aryl aldehyde to give **89**.[1473]

Samarium iodide promotes this addition reaction.[1474] In a related reaction, simple alkene units add to esters in the presence of sodium and liquid ammonia to give an alcohol.[1475] Structural variations in the alkene lead to different products. Homoallylic alcohols react with aldehydes in the presence of Montmorillonite KSF clay to give 4-hydroxytetrahydropyrans.[1476] A variation of this reaction converts an aryl aldehyde and a homoallylic alcohol to a 4-chlorotetrahydropyran in the presence of $InCl_3$.[1477] Homoallylic alcohols, protected as –O(CHMeOAc) react with BF_3•OEt_2 and acetic acid to give 4-acetoxytetrahydropyrans or with $SnBr_4$ to give 4-bromotetrahydropyrans.[1478] Homoallylic alcohols with a vinyl silane moiety react with $InCl_3$ and an aldehyde to give a dihydropyran.[1479]

A closely related reaction has been performed with activated aldehydes or ketones; without a catalyst such as chloral and acetoacetic ester, but with heat.[1480] The product in these cases is a β-hydroxy alkene, and the mechanism is pericyclic:[1481]

This reaction is reversible and suitable β-hydroxy alkenes can be cleaved by heat (**17-32**). There is evidence that the cleavage reaction occurs by a cyclic mechanism (p. 1551), and, by the principle of microscopic reversibility, the addition mechanism should be cyclic too.[1482] Note that this reaction is an oxygen analog of the ene synthesis (**15-23**). This reaction can also be done with unactivated aldehydes[1483] and ketones[1484] if Lewis-acid catalysts such as dimethylaluminum chloride (Me_2AlCl) or ethylaluminum dichloride ($EtAlCl_2$) are used.[1485] Lewis acid catalysts

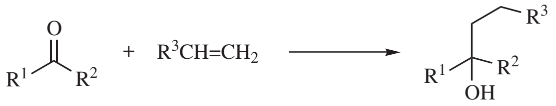
also increase rates with activated aldehydes.[1486] The use of optically active catalysts has given optically active products with high ee.[1487]



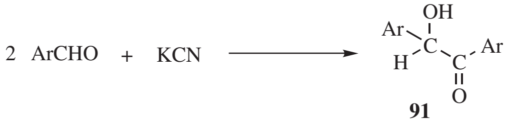
90

In a related reaction, alkenes can be added to aldehydes and ketones to give reduced alcohols **90**. This has been accomplished by several methods,[1488] including treatment with SmI_2[1489] or Zn and Me_3SiCl,[1490] and by electrochemical[1491] and photochemical[1492] methods. Most of these methods have been used for intramolecular addition and most or all involve free-radical intermediates.

OS **IV**, 786. See also, OS **VII**, 102.

16-55 The Benzoin Condensation

Benzoin aldehyde condensation



91

When certain aldehydes are treated with cyanide ion, *benzoins* (**91**) are produced in a reaction called the *benzoin condensation*. The condensation can be regarded as involving the addition of one molecule of aldehyde to the C=O group of another. The reaction only occurs with aromatic aldehydes, but not all of them,[1493] and for glyoxals RCOCHO. The two molecules of aldehyde obviously perform different functions. The one that no longer has a C—H bond in the product is called the *donor*, because it has "donated" its hydrogen to the oxygen of the other molecule, the *acceptor*. Some aldehydes can perform only one of these functions, and hence cannot be self-condensed, though they can often be condensed with a different aldehyde. For example, *p*-dimethylaminobenzaldehyde is not an acceptor but only a donor. Thus it cannot condense with itself, but it can condense with benzaldehyde, which can perform both functions, but is a better acceptor than it is a donor.

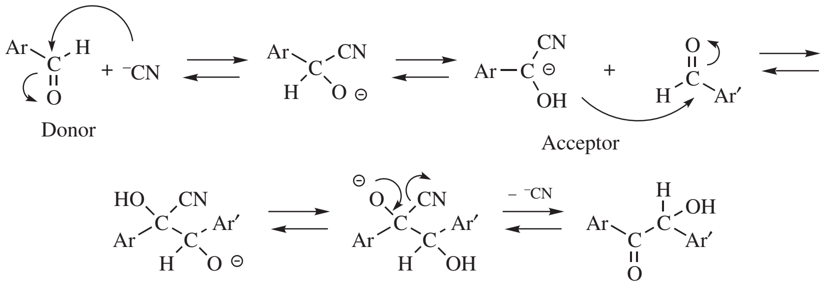
[1493]For a review, see Ide, W.S.; Buck, J.S. *Org. React.* ***1948***, *4*, 269.

The following is the accepted mechanism[1494] for this reversible reaction, which was originally proposed by Lapworth in 1903:[1495]



The key step, the loss of the aldehydic proton, can take place because the acidity of this C—H bond is increased by the electron-withdrawing power of the CN group. Thus, cyanide is a highly specific catalyst for this reaction, because, almost uniquely, it can perform three functions: (*1*) It acts as a nucleophile; (*2*) its electron-withdrawing ability permits loss of the aldehydic proton; and (*3*) having done this, it then acts as a leaving group. Certain thiazolium salts can also catalyze the reaction.[1496] In this case, aliphatic aldehydes can also be used[1497] (the products are called *acyloins*), and mixtures of aliphatic and aromatic aldehydes give mixed α-hydroxy ketones.[1498] The reaction has also been carried out without cyanide, by using the benzoylated cyanohydrin as one of the components in a phase-transfer catalyzed process. By this means, products can be obtained from aldehydes that normally fail to self-condense.[1499] The condensation has also been done with excellent enantioselectivity using benzoylformate decarboxylase.[1500] Using aryl silyl ketones, ArC(=O)$SiMe_2Ph$, and aldehydes with a lanthanum catalyst, a ‘mixed’ benzoin condensation has been accomplished.[1501]

16-56 Addition of Radicals to C=O, C=S, C=N Compounds

Radical cyclization is not limited to reaction with a C=C unit (see **15-29** and **15-30**), and reactions with both C=N and C=O moieties are known. Reaction of MeON=CH$(CH_2)_3$CHO with Bu_3SnH and AIBN, for example, led to *trans*-2-(methoxyamino)cyclopentanol in good yield.[1502] Conjugated ketones add to aldehyde via the β-carbon under radical conditions (2 equivalents of Bu_3SnH and 0.1 equivalent of CuCl) to give a β-hydroxy ketone.[1503] Addition of radical to the C=N unit of R—C=N—SPh[1504] or R—C=N—OBz[1505] led to cyclic imines. Radical addition to simple imines leads to aminocycloalkenes.[1506] Radical also add to the carbonyl unit of phenylthio esters to give cyclic ketones.[1507]

N,N-Dimethylaniline reacts with aldehydes under photochemical conditions to give acyl addition via the carbon atom of one of the methyl groups.[1508] The reaction of $PhNMe_2$ and benzaldehyde, for example, gave PhN(Me)CH_2CH(OH)Ph upon photolysis.

ACYL SUBSTITUTION REACTIONS

A. O, N, and S Nucleophiles

16-57 Hydrolysis of Acyl Halides

Hydroxy-de-halogenation

$$\text{RCOCl} + \text{H}_2\text{O} \longrightarrow \text{RCOOH}$$

Acyl halides are so reactive that hydrolysis is easily carried out.[1509] In fact, most simple acyl halides must be stored under anhydrous conditions lest they react with water in the air. Consequently, water is usually a strong enough nucleophile for the reaction, though in difficult cases hydroxide ion may be required. The reaction is seldom synthetically useful, because acyl halides are normally prepared from acids. The reactivity order is $F < Cl < Br < I$.[1510] If a carboxylic acid is used as the nucleophile, an exchange may take place (see **16-79**). The mechanism[1510] of hydrolysis can be either S_N1 or tetrahedral, the former occurring in highly polar solvents

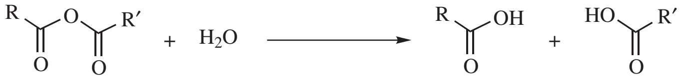
and in the absence of strong nucleophiles.[1511] There is also evidence for the S_N2 mechanism in some cases.[1512]

Hydrolysis of acyl halides is not usually catalyzed by acids, except for acyl fluorides, where hydrogen bonding can assist in the removal of F.[1513] There are several methods available for the hydrolysis of acyl fluorides.[1514]

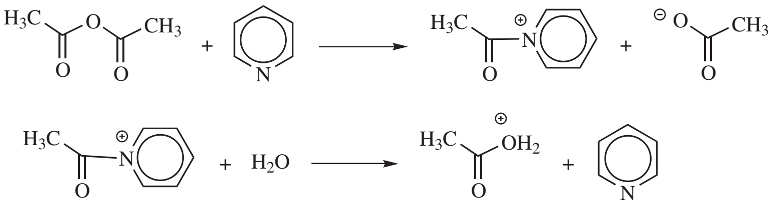
OS **II**, 74.

16-58 Hydrolysis of Anhydrides

Hydroxy-de-acyloxy-substitution



Anhydrides are somewhat more difficult to hydrolyze than acyl halides, but here too water is usually a strong enough nucleophile. The mechanism is usually tetrahedral.[1515] Only under acid catalysis does the S_N1 mechanism occur and seldom even then.[1516] Anhydride hydrolysis can also be catalyzed by bases. Of course, hydroxide ion attacks more readily than water, but other bases can also catalyze the reaction. This phenomenon, called *nucleophilic catalysis* (p. 1258), is actually the result of two successive tetrahedral mechanisms. For example, pyridine catalyzes the hydrolysis of acetic anhydride in this manner.[1517]



Many other nucleophiles similarly catalyze the reaction.

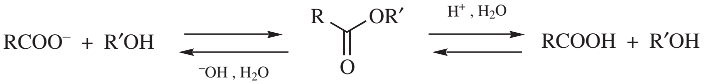
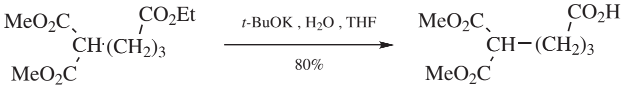
16-59 Hydrolysis of Carboxylic Esters

Hydroxy-de-alkoxylation



Ester hydrolysis is usually catalyzed by acids or bases. Since OR is a much poorer leaving group than halide or OCOR, water alone does not hydrolyze most esters. When bases catalyze the reaction, the attacking species is the more powerful nucleophile $^{-}$OH. This reaction is called *saponification* and gives the salt of the acid. Acids catalyze the reaction by making the carbonyl carbon more positive and therefore more susceptible to attack by the nucleophile. Both reactions are equilibrium reactions, so they are practicable only when there is a way of shifting the equilibrium to the right. Since formation of the salt does just this, ester hydrolysis is almost always done for preparative purposes in basic solution, unless the compound is base sensitive. Even in the case of **92**, however, selective base hydrolysis of the ethyl ester gave an 80%



92 **93**

yield of the acid-dimethyl ester (**93**).[1518] Ester hydrolysis can also be catalyzed[1519] by metal ions, by cyclodextrins,[1520] by enzymes,[1521] and by nucleophiles.[14] Other reagents used to cleave carboxylic esters include Dowex-50,[1522] Me_3SiI,[1523] and $InCl_3$ on moist silica gel using microwave irradiation.[1524] Cleavage of phenolic esters is usually faster than carboxylic esters derived from aliphatic acids. The reagent Sm/I_2 at $-78°C$ has been used,[1525] ammonium acetate in aqueous methanol,[1526]

Amberlyst 15 in methanol,[1527] and phenolic esters have been selectively hydrolyzed in the presence of alkyl esters on alumina with microwave irradiation.[1528] Thiophenol with K_2CO_3 in NMP quantitatively converted methyl benzoate to benzoic acid.[1529] Allylic esters were cleaved with 2% Me_3SiOTf in dichloromethane,[1530] with $CeCl_3$•7 H_2O—NaI,[1531] and with $NaHSO_4$•silica gel.[1532] Lactones also undergo the reaction[1533] (though if the lactone is five- or six-membered, the hydroxy acid often spontaneously reforms the lactone) and thiol esters (RCOSR′) give thiols R′SH. Typical reagents for this latter transformation include NaSMe in methanol,[1534] borohydride exchange resin-Pd$(OAc)_2$ for reductive cleavage of thiol esters to thiols,[1535] and $TiCl_4$/Zn for the conversion of phenylthioacetates to thiophenols.[1536] Sterically hindered esters are hydrolyzed with difficulty (p. 479), but reaction of 2 equivalents of *t*-BuOK with 1 equivalent of water is effective.[1537] Hindered esters can also be cleaved by sequential treatment with zinc bromide and then water,[1538] with silica gel in refluxing toluene,[1539] and on alumina when irradiated with microwaves.[1540] For esters insoluble in water the rate of two-phase ester saponification can be greatly increased by the application of ultrasound,[1541] and phase-transfer techniques have been applied.[1542] Enzymatic hydrolysis of diesters with esterase has been shown to give the hydroxy ester,[1543] and selective hydrolysis of dimethyl succinate to monomethyl succinic acid was accomplished with aq. NaOH in THF.[1544] Hydrolysis of vinyl esters leads to ketones, and the reaction of C-substituted vinyl acetates with an esterase derived from *Marchantia polymorpha* gave substituted ketones with high enantioselectivity.[1545] Scandium triflate was shown to hydrolyze α-acetoxy ketones to α-hydroxy ketones.[1546]

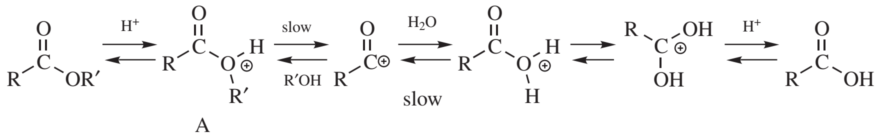
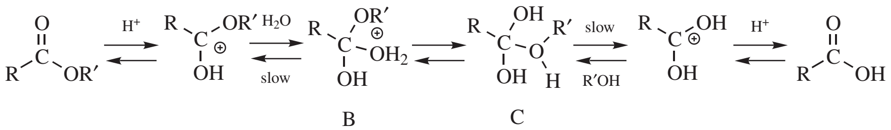
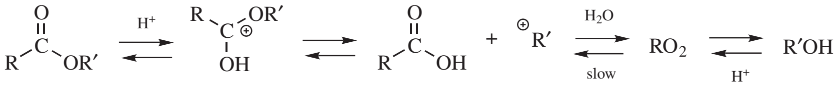
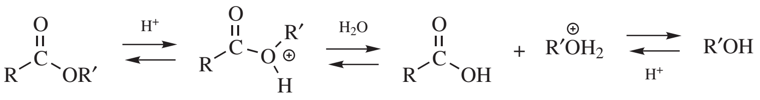
Ingold[1547] has classified the acid- and base-catalyzed hydrolyses of esters (and the formation of esters, since these are reversible reactions and thus have the same mechanisms) into eight possible mechanisms (Table 16.3), depending on the

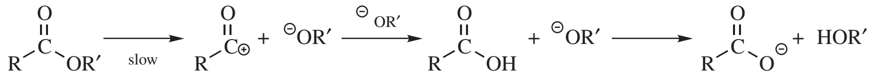
TABLE 16.3. Classification of the Eight Mechanisms for Ester Hydrolysis and Formation[1547]

Name		
Ingold	IUPAC[1548]	Type
$A_{AC}1$	$A_h + D_N + A_N + D_h$	S_N1
		


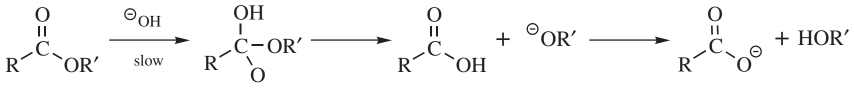
$A_{AC}2$	$A_h + A_N + A_hD_h + D_h$	Tetrahedral
		


$A_{AL}1$	$A_h + D_N + A_N + D_h$	S_N1
		


$A_{AL}2$	$A_h + A_ND_N + D_h$	S_N2
		


$B_{AC}1$	$D_N + A_N + A_{xh}D_h$	S_N1
		


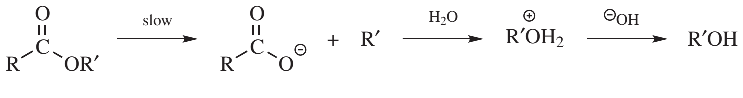
$B_{AC}2$	$A_N + D_N + A_{xh}D_h$	Tetrahedral
		



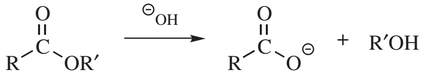
[1547]Ingold, C.K. *Structure and Mechanism in Organic Chemistry*, 2nd ed., Cornell University Press, Ithaca, NY, ***1969***, pp. 1129–1131.

[1548]As given here, the IUPAC designations for $B_{AC}1$ and $B_{AL}1$ are the same, but Rule A.2 adds further symbols so that they can be distinguished: Su-AL for $B_{AL}1$ and Su-AC for $B_{AC}1$. See the IUPAC rules: Guthrie, R.D. *Pure Appl. Chem.* ***1989***, *61*, 23, see p. 49.

TABLE 16.3. (*Continued*)

Name		
Ingold	IUPAC	Type
$B_{AL}1$	$D_N + A_N + A_{xh}D_h$	S_N1
		


$B_{AL}2$	A_ND_N	S_N2
		



following criteria: (*1*) acid- or base-catalyzed, (*2*) unimolecular or bimolecular, and (*3*) acyl cleavage or alkyl cleavage.[1549] All eight of these are S_N1, S_N2, or tetrahedral mechanisms. The acid-catalyzed mechanisms are shown with reversible arrows. They are not only reversible, but symmetrical; that is, the mechanisms for ester formation are exactly the same as for hydrolysis, except that H replaces R. Internal proton transfers, such as shown for **B** and **C**, may not actually be direct but may take place through the solvent. There is much physical evidence to show that esters are initially protonated on the carbonyl and not on the alkyl oxygen (Chapter 8, Ref. 17). We have nevertheless shown the $A_{AC}1$ mechanism as proceeding through the ether-protonated intermediate **A**, since it is difficult to envision OR′ as a leaving group here. It is of course possible for a reaction to proceed through an intermediate even if only a tiny concentration is present. The designations $A_{AC}1$, and so on., are those of Ingold. The $A_{AC}2$ and $A_{AC}1$ mechanisms are also called A2 and A1, respectively. Note that the $A_{AC}1$ mechanism is actually the same as the S_N1cA mechanism for this type of substrate and that $A_{AL}2$ is analogous to S_N2cA. Some authors use A1 and A2 to refer to all types of nucleophilic substitution in which the leaving group first acquires a proton. The base-catalyzed reactions are not shown with reversible arrows, since they are reversible only in theory and not in practice. Hydrolyses taking place under neutral conditions are classified as B mechanisms.

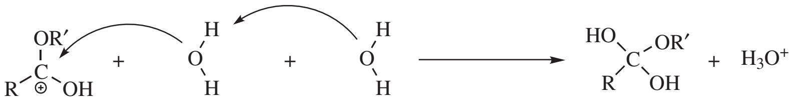
Of the eight mechanisms, seven have actually been observed in hydrolysis of carboxylic esters. The one that has not been observed is the $B_{AC}1$ mechanism.[1550] The most common mechanisms are the $B_{AC}2$ for basic catalysis and the $A_{AC}2$[1551]

[1549]For reviews of the mechanisms of ester hydrolysis and formation, see Kirby, A.J., in Bamford, C.H.; Tipper, C.F.H., *Comprehensive Chemical Kinetics*, Vol. 10, ***1972***, pp. 57–207; Euranto, E.K., in Patai, S. *The Chemistry of Carboxylic Acids and Esters*, Wiley, NY, ***1969***, pp. 505–588.

[1550]This is an S_N1 mechanism with OR′ as leaving group, which does not happen.

[1551]For a discussion of this mechanism with specific attention to the proton transfers involved, see Zimmermann, H.; Rudolph, J. *Angew. Chem. Int. Ed.* ***1965***, *4*, 40.

for acid catalysis, that is, the two tetrahedral mechanisms. Both involve acyl-oxygen cleavage. The evidence is (*1*) hydrolysis with $H_2{}^{18}O$ results in the ^{18}O appearing in the acid and not in the alcohol;[1552] (*2*) esters with chiral R′ groups give alcohols with *retention* of configuration;[1553] (*3*) allylic R′ gives no allylic rearrangement;[1554] (*4*) neopentyl R′ gives no rearrangement;[1555] all these facts indicate that the O—R′ bond is not broken. It has been concluded that two molecules of water are required in the $A_{AC}2$ mechanism.



If this is so, the protonated derivatives **B** and **C** would not appear at all. This conclusion stems from a value of *w* (see p. 371) of ~5, indicating that water acts as a proton donor here, as well as a nucleophile.[1556] Termolecular processes are rare, but in this case the two water molecules are already connected by a hydrogen bond. (A similar mechanism, called $B_{AC}3$, also involving two molecules of water, has been found for esters that hydrolyze without a catalyst.[1557] Such esters are mostly those containing halogen atoms in the R group.)

The other mechanism involving acyl cleavage is the $A_{AC}1$ mechanism. This is rare, being found only where R is very bulky, so that bimolecular attack is sterically hindered, and only in ionizing solvents. The mechanism has been demonstrated for esters of 2,4,6-trimethylbenzoic acid (mesitoic acid). This acid depresses the freezing point of sulfuric acid four times as much as would be predicted from its molecular weight, which is evidence for the equilibrium

$$\text{ArCOOH} + 2\,H_2SO_4 \rightleftharpoons \text{ArCO}^{\oplus} + H_3O^+ + 2\,HSO_4^-$$

In a comparable solution of benzoic acid the freezing point is depressed only twice the predicted amount, indicating only a normal acid-base reaction. Further, a sulfuric acid solution of methyl mesitoate when poured into water gave mesitoic acid, while a similar solution of methyl benzoate similarly treated did not.[1558] The $A_{AC}1$ mechanism is also found when acetates of phenols or of primary alcohols are

[1558]Treffers, H.P.; Hammett, L.P. *J. Am. Chem. Soc.* ***1937***, *59*, 1708. For other evidence for this mechanism, see Bender, M.L.; Chen, M.C. *J. Am. Chem. Soc.* ***1963***, *85*, 37.

hydrolyzed in concentrated (>90%) H_2SO_4 (the mechanism under the more usual dilute acid conditions is the normal $A_{AC}2$).[1559]

The mechanisms involving alkyl-oxygen cleavage are ordinary S_N1 and S_N2 mechanisms in which OCOR (an acyloxy group) or its conjugate acid is the leaving group. Two of the three mechanisms, the $B_{AL}1$ and $A_{AL}1$ mechanisms, occur most readily when R′ comes off as a stable carbocation, that is, when R′ is tertiary alkyl, allylic, benzylic, and so on. For acid catalysis, most esters with this type of alkyl group (especially tertiary alkyl) cleave by this mechanism, but even for these substrates, the $B_{AL}1$ mechanism occurs only in neutral or weakly basic solution, where the rate of attack by hydroxide is so slowed that the normally slow (by comparison) unimolecular cleavage takes over. These two mechanisms have been established by kinetic studies, ^{18}O labeling, and isomerization of R′.[1560] Secondary and benzylic acetates hydrolyze by the $A_{AC}2$ mechanism in dilute H_2SO_4, but in concentrated acid the mechanism changes to $A_{AL}1$.[1559] Despite its designation, the $B_{AL}1$ mechanism is actually uncatalyzed (as is the unknown $B_{AC}1$ mechanism).

The two remaining mechanisms, $B_{AL}2$ and $A_{AL}2$, are very rare, the $B_{AL}2$ because it requires hydroxide ion to attack an alkyl carbon when an acyl carbon is also available,[1561] and the $A_{AL}2$ because it requires water to be a nucleophile in an S_N2 process. Both have been observed, however. The $B_{AL}2$ has been seen in the hydrolysis of β-lactones under neutral conditions[1562] (because cleavage of the C—O bond in the transition state opens the four-membered ring and relieves strain), the alkaline hydrolysis of methyl 2,4,6-tri-*tert*-butyl benzoate,[1563] and in the unusual reaction[1564]

$$ArCOOMe + RO^- \longrightarrow ArCOO^- + ROMe$$

When it does occur, the $B_{AL}2$ mechanism is easy to detect, since it is the only one of the base-catalyzed mechanisms that requires inversion at R′. However, in the last example given, the mechanism is evident from the nature of the product, since the ether could have been formed in no other way. The $A_{AL}2$ mechanism has been reported in the acid cleavage of γ-lactones.[1565]

To sum up the acid-catalysis mechanisms, $A_{AC}2$ and $A_{AL}1$ are the common mechanisms, the latter for R′ that give stable carbocations, the former for practically

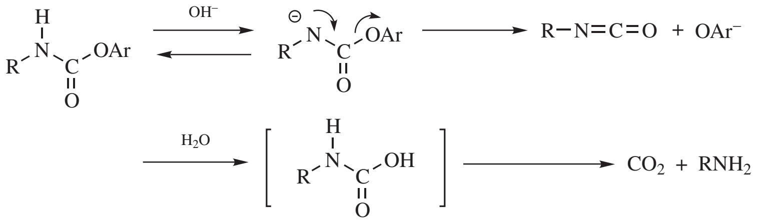
all the rest. The $A_{AC}1$ mechanism is rare, being found mostly with strong acids and sterically hindered R. The $A_{AL}2$ mechanism is even rarer. For basic catalysis, $B_{AC}2$ is almost universal; $B_{AL}1$ occurs only with R′ that give stable carbocations and then only in weakly basic or neutral solutions; $B_{AL}2$ is very rare; and $B_{AC}1$ has never been observed.

The above results pertain to reactions in solution. In the gas-phase[1566] reactions can take a different course, as illustrated by the reaction of carboxylic esters with MeO^-, which in the gas phase was shown to take place only by the $B_{AL}2$ mechanism,[1567] even with aryl esters,[1568] where this means that an S_N2 mechanism takes place at an aryl substrate. However, when the gas-phase reaction of aryl esters was carried out with MeO^- ions, each of which was solvated with a single molecule of MeOH or H_2O, the $B_{AC}2$ mechanism was observed.[1567]

In the special case of alkaline hydrolysis of *N*-substituted aryl carbamates, there is another mechanism[1569] involving elimination–addition:[1570]



This mechanism does not apply to unsubstituted or *N,N*-disubstituted aryl carbamates, which hydrolyze by the normal mechanisms. Carboxylic esters substituted in the a position by an electron-withdrawing group (e.g., CN or COOEt) can also hydrolyze by a similar mechanism involving a ketene intermediate.[1571]

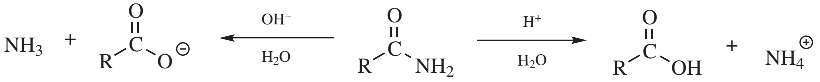
These elimination–addition mechanisms usually are referred to as E1cB mechanisms, because that is the name given to the elimination portion of the mechanism (p. 1488).

The acid-catalyzed hydrolysis of enol esters RCOOCR′=CR can take place either by the normal $A_{AC}2$ mechanism or by a mechanism involving initial protonation on the double-bond carbon, similar to the mechanism for the hydrolysis of enol ethers given in **10-6**,[1572] depending on reaction conditions.[1573] In either case, the products are the carboxylic acid RCOOH and the aldehyde or ketone R–CHCOR′.

OS **I**, 351, 360, 366, 379, 391, 418, 523; **II**, 1, 5, 53, 93, 194, 214, 258, 299, 416, 422, 474, 531, 549; **III**, 3, 33, 101, 209, 213, 234, 267, 272, 281, 300, 495, 510, 526, 531, 615, 637, 652, 705, 737, 774, 785, 809 (but see OS **V**, 1050), 833, 835; **IV**, 15, 55, 169, 317, 417, 444, 532, 549, 555, 582, 590, 608, 616, 628, 630, 633, 635, 804; **V**, 8, 445, 509, 687, 762, 887, 985, 1031; **VI**, 75, 121, 560, 690, 824, 913, 1024; **VII**, 4, 190, 210, 297, 319, 323, 356, 411; **VIII**, 43, 141, 219, 247, 258, 263, 298, 486, 516, 527. Ester hydrolyses with concomitant decarboxylation are listed at reaction **12-40**.

16-60 Hydrolysis of Amides

Hydroxy-de-amination



Unsubstituted amides ($RCONH_2$) can be hydrolyzed with either acidic or basic catalysis, the products being, respectively, the free acid and the ammonium ion or the salt of the acid and ammonia. *N*-Substituted (RCONHR′) and *N,N*-disubstituted ($RCONR''_2$) amides can be hydrolyzed analogously, with the primary or secondary amine, respectively (or their salts), being obtained instead of ammonia. Lactams, imides, cyclic imides, hydrazides, and so on., also undergo the reaction. Water alone is not sufficient to hydrolyze most amides,[1574] since NH_2 is even a poorer leaving group than OR.[1575] Prolonged heating is often required, even with acidic or basic catalysts.[1576] Treatment of primary

[1572]Alkynyl esters also hydrolyze by this mechanism; see Allen, A.D.; Kitamura, T.; Roberts, K.A.; Stang, P.J.; Tidwell, T.T. *J. Am. Chem. Soc.* ***1988***, *110*, 622.

[1573]See, for example, Noyce, D.S.; Pollack, R.M. *J. Am. Chem. Soc.* ***1969***, *91*, 119, 7158; Monthéard, J.; Camps, M.; Chatzopoulos, M.; Benzaïd, A. *Bull. Soc. Chim. Fr.* ***1984***, II-109. For a discussion, see Euranto, E.K. *Pure Appl. Chem.* ***1977***, *49*, 1009.

[1574]See Zahn, D. *Eur. J. Org. Chem.* ***2004***, 4020.

[1575]The very low rate of amide hydrolysis by water alone has been measured: Kahne, D.; Still, W.C. *J. Am. Chem. Soc.* ***1988***, *110*, 7529.

[1576]For a list of catalysts and reagents that have been used to hydrolyze amides, with references, see Larock, R.C. *Comprehensive Organic Transformatinos*, 2nd ed., Wiley-VCH, NY, ***1999***, pp. 1976–1977. Also see, Bagno, A.; Lovato, G.; Scorrano, G. *J. Chem. Soc. Perkin Trans. 2* ***1993***, 1091.

amides with phthalic anhydride at 250°C and 4 atm gives the carboxylic acid and phthalimide.[1577] The conversion of acylhydrazine derivatives to the corresponding carboxylic acid with PhI(OH)(OTs) and water is a variation of amide hydrolysis.[1578] Hydrolysis of carbamates ($RNHCO_2R$) to the corresponding amine can be categorized in this section. Although the product is an amine and the carboxyl unit fragments, this reaction is simply a variation of amide hydrolysis. Strong acids, such as trifluoroacetic acid (in dichloromethane), are usually employed.[1579] Treatment of *N*-Boc derivatives ($RNHCO_2t$-Bu) with $AlCl_3$[1580] or with aqueous sodium *tert*-butoxide[1581] gave the amine. The by-products of this reaction are typically carbon dioxide and isobutylene.

In difficult cases, nitrous acid, NOCl, N_2O_4,[1582] or a similar compound can be used (unsubstituted amides only[1583]).These reactions involve a diazonium ion (see **13-19**) and are much faster than ordinary hydrolysis; for benzamide the nitrous acid reaction took place 2.5×10^7 times faster than ordinary hydrolysis.[1584] Another procedure for difficult cases involves treatment with aqueous sodium peroxide.[1585] In still another method, the amide is treated with water and *t*-BuOK at room temperature.[1586] The strong base removes the proton from **107**, thus preventing the reaction marked k_{-1}. A kinetic study has been done on the alkaline hydrolyses of *N*-trifluoroacetyl aniline derivatives.[1587] Amide hydrolysis can also be catalyzed by nucleophiles (see p. 1259).

The same framework of eight possible mechanisms that was discussed for ester hydrolysis can also be applied to amide hydrolysis.[1588] Both the acid- and base-catalyzed hydrolyses are essentially irreversible, since salts are formed in both

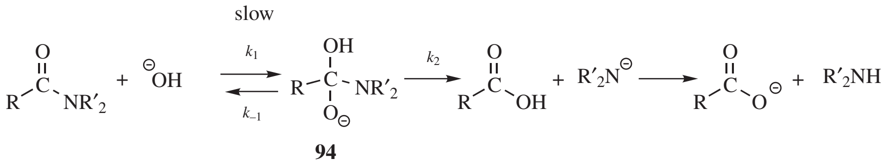
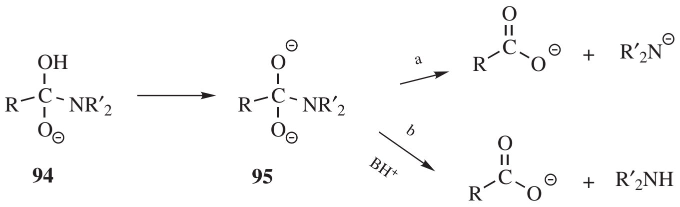
cases. For basic catalysis,[1589] the mechanism is $B_{AC}2$.



There is much evidence for this mechanism, similar to that discussed for ester hydrolysis. A molecular-orbital study on the mechanism of amide hydrolysis is available.[1590] In certain cases, kinetic studies have shown that the reaction is second order in OH^-, indicating that **94** can lose a proton to give **95**.[1591] Depending on the nature



of R′, **95** can cleave directly to give the two negative ions (path *a*) or become *N*-protonated prior to or during the act of cleavage (path *b*), in which case the products are obtained directly and a final proton transfer is not necessary.[1592] Studies of the effect, on the rate of hydrolysis and on the ratio k_{-1}/k_2, of substituents on the aromatic rings in a series of amides $CH_3CONHAr$ led to the conclusion that path *a* is taken when Ar contains electron-withdrawing substituents and path *b* when electron-donating groups are present.[1593] The presence of electron-withdrawing groups helps stabilize the negative charge on the nitrogen, so that $NR_2'^-$ can be a leaving group (path *a*). Otherwise, the C—N bond does not cleave until the nitrogen is protonated (either prior to or in the act of cleavage), so that the leaving group, *even in the base-catalyzed reaction*, is not $NR_2'^-$ but the conjugate NHR_2'(path *b*). Though we have shown formation of **94** as the rate-determining step in the $B_{AC}2$ mechanism, this is true only at high base concentrations. At lower concentrations of base, the cleavage of **107** or **95** becomes rate determining.[1594]

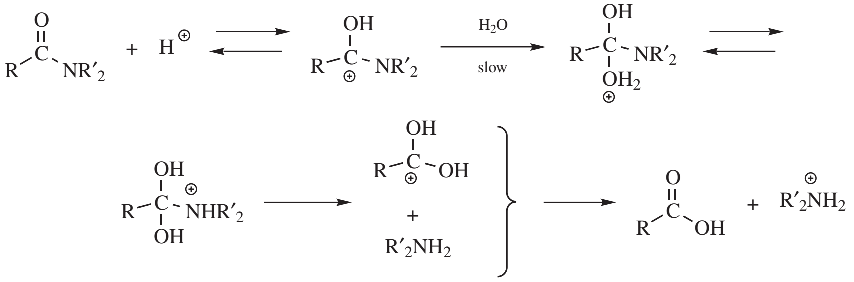
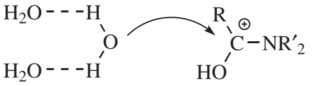
For acid catalysis, matters are less clear. The reaction is generally second order, and it is known that amides are primarily protonated on the oxygen (Chapter 8, Ref. 24). Because of these facts it has been generally agreed that most acid-catalyzed amide hydrolysis takes place by the $A_{AC}2$ mechanism.



Further evidence for this mechanism is that a small but detectable amount of ^{18}O exchange (see p. 1256) has been found in the acid-catalyzed hydrolysis of benzamide.[1595] (^{18}O exchange has also been detected for the base-catalyzed process,[1596] in accord with the $B_{AC}2$ mechanism). Kinetic data have shown that three molecules of water are involved in the rate-determining step,[1597] suggesting that, as in the $A_{AC}2$ mechanism for ester hydrolysis (**16-59**), additional water molecules take part in a process, such as



The four mechanisms involving alkyl—N cleavage (the AL mechanisms) do not apply to this reaction. They are not possible for unsubstituted amides, since the only N—C bond is the acyl bond. They are possible for *N*-substituted and *N,N*-disubstituted amides, but in these cases they give entirely different products and are not amide hydrolyses at all.

This reaction, while rare, has been observed for various *N-tert*-butylamides in 98% sulfuric acid, where the mechanism was the $A_{AL}1$ mechanism,[1598] and for certain amides containing an azo group, where a $B_{AL}1$ mechanism was postulated.[1599] Of the two first-order acyl cleavage mechanisms, only the $A_{AC}1$ has been observed, in concentrated sulfuric acid solutions.[1600] Of course, the diazotization of unsubstituted amides might be expected to follow this mechanism, and there is evidence that this is true.[1584]

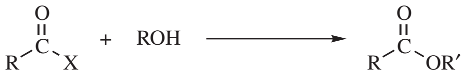
OS **I**, 14, 111, 194, 201, 286; **II**, 19, 25, 28, 49, 76, 208, 330, 374, 384, 457, 462, 491, 503, 519, 612; **III**, 66, 88, 154, 256, 410, 456, 586, 591, 661, 735, 768, 813; **IV**, 39, 42, 55, 58, 420, 441, 496, 664; **V**, 27, 96, 341, 471, 612, 627; **VI**, 56, 252, 507, 951, 967; **VII**, 4, 287; **VIII**, 26, 204, 241, 339, 451.

The oxidation of aldehydes to carboxylic acids can proceed by a nucleophilic mechanism, but more often it does not. The reaction is considered in Chapter 19 (**19-23**). Basic cleavage of β-keto esters and the haloform reaction could be considered at this point, but they are also electrophilic substitutions and are treated in Chapter 12 (**12-43** and **12-44**).

B. Attack by OR at an Acyl Carbon

16-61 Alcoholysis of Acyl Halides

Alkoxy-de-halogenation



The reaction between acyl halides and alcohols or phenols is the best general method for the preparation of carboxylic esters. It is believed to proceed by a S_N2 mechanism.[1601] As with **16-57**, the mechanism can be S_N1 or tetrahedral.[1510] Pyridine catalyzes the reaction by the nucleophilic catalysis route (see **16-58**). Lewis acids such as lithium perchlorate can be used.[1602] The reaction is of wide scope, and many functional groups do not interfere. A base is frequently added to combine with the HX formed. When aqueous alkali is used, this is called the *Schotten–Baumann procedure*, but pyridine is also frequently used. Both R and R′ may be primary, secondary, or tertiary alkyl or aryl. Enol esters can also be prepared by this method, though *C*-acylation competes in these cases. In difficult cases, especially with hindered acids or tertiary R′, the alkoxide can be used instead of the alcohol.[1603] Activated alumina has also been used as a catalyst, for

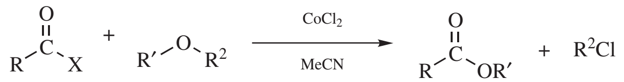
tertiary R′.[1604] Thallium salts of phenols give very high yields of phenolic esters,[1605] and BiOCl is very effective for the preparation of phenolic acetates.[1606] Phase-transfer catalysis has been used for hindered phenols.[1607] Zinc has been used to couple alcohols and acyl chlorides,[1608] and catalytic $Cu(acac)_2$ and benzoyl chloride was used to prepare the mono-benzoate of ethylene glycol.[1609] Selective acylation is possible in some cases.[1610]

Acyl halides react with thiols, in the presence of zinc, to give the corresponding thio-ester.[1611] The reaction of acid chlorides or anhydrides (see **16-62**) with diphenyldiselenide, in the presence of $Sm/CoCl_2$[1612] or $Sm/CrCl_3$[1613] gave the corresponding seleno ester (PhSeCOMe).

Acyl halides can also be converted to carboxylic acids by using ethers instead of alcohols, in MeCN in the presence of certain catalysts such as cobalt(II) chloride.[1614] A variation of this reaction has been reported that uses acetic anhydride.[1615]

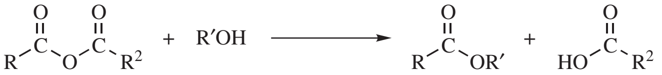


This is a method for the cleavage of ethers (see also, **10-49**).

OS **I**, 12; **III**, 142, 144, 167, 187, 623, 714; **IV**, 84, 263, 478, 479, 608, 616, 788; **V**, 1, 166, 168, 171; **VI**, 199, 259, 312, 824; **VII**, 190; **VIII**, 257, 516.

16-62 Alcoholysis of Anhydrides

Alkoxy-de-acyloxy-substitution



The scope of this reaction is similar to that of **16-61**. Anhydrides are somewhat less reactive than acyl halides, and they are often used to prepare carboxylic esters. Benzyl acetates have been prepared via microwave irradiation of benzylic alcohols

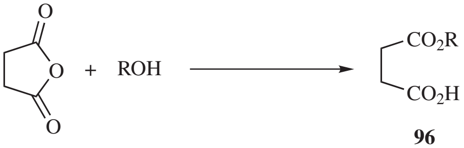
and acetic anhydride.[1616] Acids,[1617] Lewis acids,[1618] and bases, such as pyridine are often used as catalysts.[1619] Acetic anhydride and $NiCl_2$ with microwave irradiation converts benzylic alcohols to the corresponding acetate.[1620] The monoacetate of 1,2-diols have been prepared using $CeCl_3$ as a catalyst.[1621] Pyridine is a nucleophilic-type catalyst (see **16-58**). 4-(*N,N*-Dimethylamino)pyridine is a better catalyst and can be used in cases where pyridine fails.[1622] *N*-Bromosuccinimide has been shown to catalyzed esterification of alcohols with acetic anhydride.[1623] Formic anhydride is not a stable compound but esters of formic acid can be prepared by treating alcohols[1624] or phenols[1625] with acetic-formic anhydride. Cyclic anhydrides give mono-esterified dicarboxylic acids, such as **96**.[1626] The asymmetric alcoholysis of cyclic anhydrides has been reviewed.[1627]



96

Alcohols can also be acylated by mixed organic–inorganic anhydrides, such as acetic-phosphoric anhydride, $MeCOOPO(OH)_2$[1628] (see **16-68**). Thioesters of the type ArS(C=O)Me have been prepared from diphenyl disulfide and PBu_3, followed by treatment with acetic anhydride.[1629]

16-63 Esterification of Carboxylic Acids

Alkoxy-de-hydroxylation

$$\text{RCOOH} \quad + \quad \text{R'OH} \quad \overset{\text{H+}}{\rightleftharpoons} \quad \text{RCOOR'} \quad + \quad \text{H}_2\text{O}$$

The esterification of carboxylic acids with alcohols[1630] is the reverse of **16-60** and can be accomplished only if a means is available to drive the equilibrium to the right.[1631] There are many ways of doing this, among which are (*1*) addition of an excess of one of the reactants, usually the alcohol; (*2*) removal of the ester or the water by distillation; (*3*) removal of water by azeotropic distillation; and (*4*) removal of water by use of a dehydrating agent, silica gel,[1632] or a molecular sieve. When R′ is methyl, the most common way of driving the equilibrium is by adding excess MeOH; when R′ is ethyl, it is preferable to remove water by azeotropic distillation.[1633] The most common catalysts are H_2SO_4 and TsOH, although some reactive acids (e.g., formic,[1634] trifluoroacetic[1635]) do not require a catalyst. Ammonium salts have been used to initiate esterification,[1636] and boric acid has been used to esterify α-hydroxy acids.[1637] The R′ group may be primary or secondary alkyl groups other than methyl or ethyl, but tertiary alcohols usually give carbocations and elimination. Phenols can sometimes be used to prepare phenolic esters, but yields are generally very low. Selective esterification of an aliphatic carboxylic acid in the presence of an aromatic acid was accomplished with $NaHSO_4{\bullet}SiO_2$ and methanol.[1638]

Diphenylammonium triflate was useful for direct esterification of carboxylic acids with longer chain aliphatic alcohols.[1639] Photoirradiation of carboxylic acid with CBr_4[1640] or CCl_4[1641] in methanol was shown to give the methyl ester, with high selectivity for nonconjugated acids in the case of CBr_4. *O*-Alkylisoureas react

with conjugated carboxylic acids to give the corresponding ester with microwave irradiation,[1642] and a polymer-bound *O*-alkylurea has been used as well.[1643]

Mixing the carboxylic acid and alcohol with *p*-toluenesulfonic acid (neat), gave the ester in 3 min with microwave irradiation.[1644] Esterification has also been accomplished using ionic liquids as the reaction medium,[1645] and a solid-state esterification was reported on P_2O_5/SiO_2.[1646] Diols are converted to the mono-acetate by heating with acetic acid on a zeolite.[1647]

97

Both γ- and δ-hydroxy acids such as **97** are easily converted to a lactone by treatment with acids, or often simply on standing, but larger and smaller lactone rings cannot be made in this manner, because polyester formation occurs more readily.[1648] Often the conversion of a group, such as keto or halogen, γ or δ to a carboxyl group, to a hydroxyl group gives the lactone directly, since the hydroxy acid cyclizes too rapidly for isolation. β-Substituted β-hydroxy acids can be converted to β-lactones by treatment with benzenesulfonyl chloride in pyridine at 0–5°C.[1649] ε-Lactones (seven-membered rings) have been made by cyclization of ε-hydroxy acids at high dilution.[1650] Macrocyclic lactones[1651] can be prepared indirectly in very good yields by conversion of the hydroxy acids to 2-pyridinethiol esters and adding these to refluxing xylene.[1652] Palladium-catalyzed aromatic carboxylation

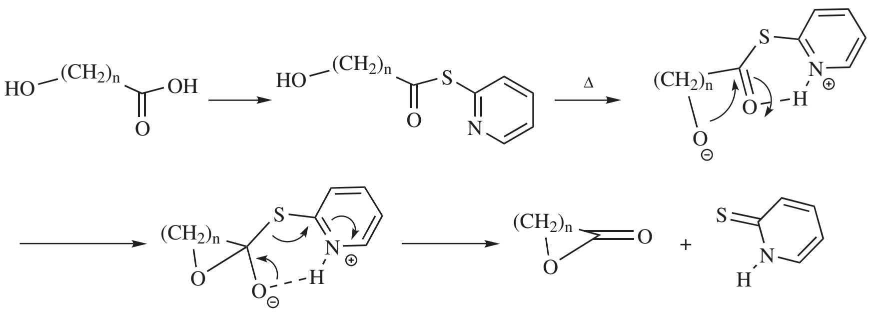
reactions generated carboxylic acids *in situ*, and when an alcohol unit is present elsewhere in the molecule cyclization gives the corresponding lactone.[1653]



A closely related method, which often gives higher yields of a macrocyclic lactone, involves treatment of the hydroxy acids with 1-methyl- or 1-phenyl-2-halopyridinium salts, especially 1-methyl-2-chloropyridinium iodide (*Mukaiyama's reagent*).[1654] Another method uses organotin oxides[1655] and both $TiCl_4/AgClO_4$[1656] and $TiCl_2(OSO_2CF_3)_2$[1657] have been used.

Esterification is catalyzed by acids (not bases) in ways that were discussed on p. 1402.[1549] The mechanisms are usually $A_{AC}2$, but $A_{AC}1$ and $A_{AL}1$ have also been observed.[1658] Certain acids, such as 2,6-di-ortho-substituted benzoic acids, cannot be esterified by the $A_{AC}2$ mechanism because of steric hindrance (p. 481). In such cases, esterification can be accomplished by dissolving the acid in 100% H_2SO_4 (forming the ion RCO^+) and pouring the solution into the alcohol ($A_{AC}1$ mechanism). The reluctance of hindered acids to undergo the normal $A_{AC}2$ mechanism can sometimes be put to advantage when, in a molecule containing two COOH groups,

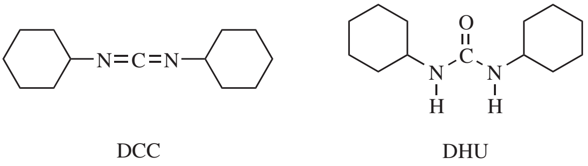
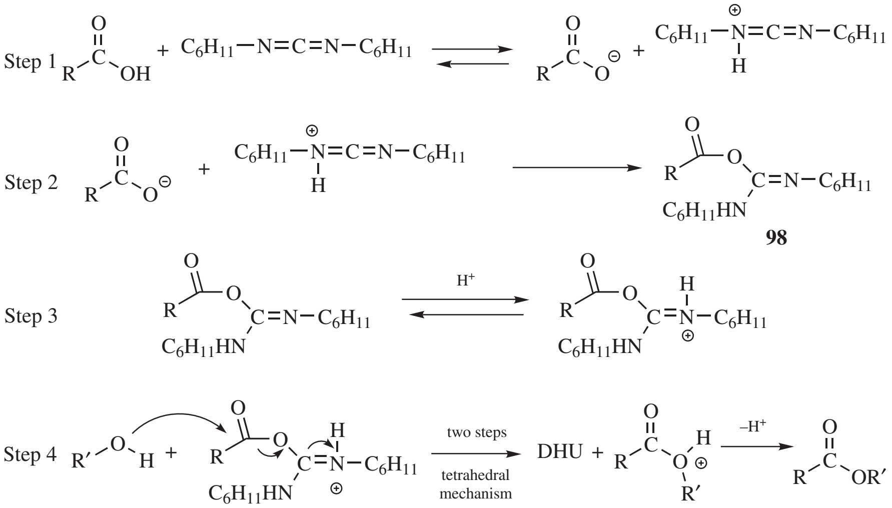
only the less hindered one is esterified. The $A_{AC}1$ pathway cannot be applied to unhindered carboxylic acids.



Another way to esterify a carboxylic acid is to treat it with an alcohol in the presence of a dehydrating agent.[1631] One of these is dicyclohexylcarbodiimide (DCC), which is converted in the process to dicyclohexylurea (DHU). The mechanism[1659] has much in common with the nucleophilic catalysis mechanism; the acid is converted to a compound with a better leaving group. However, the conversion is not by a tetrahedral mechanism (as it is in nucleophilic catalysis), since the C—O bond remains intact during this step:



Evidence for this mechanism was the preparation of *O*-acylureas similar to **98** and the finding that when catalyzed by acids they react with alcohols to give esters.[1660] Hindered tertiary alcohols can be coupled via DCC to give the hindered ester.[1661] A polymer-bound carbodiimide has been used to prepare macrocyclic lactones.[1662] In at least one case, the reaction of $HOOCCH_2CN$ with DCC and *tert*-butanol gave the *tert*-butyl ester via a ketene intermediate.[1663]

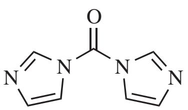
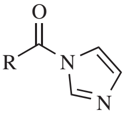
[1663]Nahmany, M.; Melman, A. *Org. Lett.* ***2001***, *3*, 3733.

There are limitations to the use of DCC; yields are variable and *N*-acylureas are side products. Many other dehydrating agents[1664] have been used, including DCC and an aminopyridine,[1665] Amberlyst-15,[1666] chlorosilanes,[1667] $MeSO_2Cl$-Et_3N,[1668] and *N*,*N*′-carbonyldiimidazole(**99**).[1669] In the latter case, imidazolides (**100**) are intermediates that readily react with alcohols.



99



100

It is known that the Lewis acid BF_3 promotes the esterification by converting the acid to RCO^+—BF_3 ^-OH, so the reaction proceeds by an $A_{AC}1$ type of mechanism. The use of BF_3-etherate is simple and gives high yields.[1670] Other Lewis acids can be used.[1671] Esterification has been done using a LaY zeolite.[1672]

Carboxylic esters can also be prepared by treating carboxylic acids with *tert*-butyl ethers and acid catalysts.[1673]

$$\text{RCOOH} \quad + \quad t\text{-Bu-OR}' \longrightarrow \text{RCOOR}' \quad + \quad \text{H}_2\text{C=CMe}_2 \quad + \text{H}_2\text{O}$$

Carboxylic acids can be converted to *tert*-butyl esters by treatment with *tert*-butyl 2,2,2-trichloroacetimidate (see **10-10**) and BF_3•OEt_2.[1173] Carboxylic esters can be formed from the carboxylate anion and a suitable alkylating agent (**10-26**).

Thioesters of the type RSC(=S)R′ (a dithiocarboxylic ester) and RSC(C=O)R′ (a thiocarboxylic ester) can be generated by reaction of carboxylic acids with thiols.

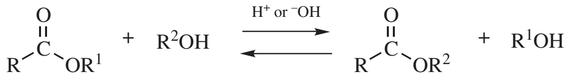
16-64 Transesterification

Alkoxy-de-alkoxylation



Transesterification[1677] is catalyzed[1678] by acids[1679] or bases,[1680] or performed under neutral conditions.[1681] It is an equilibrium reaction and must be shifted in the desired direction. In many cases low-boiling esters can be converted to higher boiling ones by the distillation of the lower boiling alcohol as fast as it is formed. Reagents used to catalyze[1682] transesterification include Montmorillonite K10[1683] and various Lewis acids.[1684] A polymer-bound siloxane has been used to induce transesterification.[1685] This reaction has been used as a method for the acylation of a primary OH in the presence of a secondary OH.[1686] Regioselectivity has

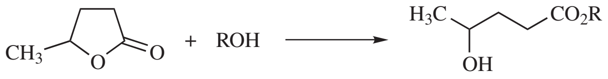
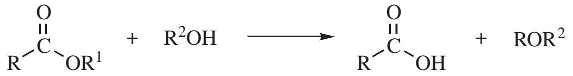
also been accomplished by using enzymes (lipases) as catalysts.[1687] Lactones, such as **101**, are easily opened by treatment with alcohols[1688] to give open-chain hydroxy esters.



101

Transesterification has been carried out with phase-transfer catalysts, without an added solvent.[1689] Nonionic superbases (see p. 365) of the type $P(RNCH_2CH_2)_3N$ catalyze the transesterification of carboxylic acid esters at 25°C.[1690] Silyl esters ($R'CO_2SiR_3$) have been converted to alkyl esters ($R'CO_2R$) via reaction with alkyl halides and tetrabutylammonium fluoride.[1691] Thioesters are converted to phenolic esters by treatment with triphosgene–pyridine and then phenol.[1692]

Transesterification occurs by mechanisms[1693] that are identical with those of ester hydrolysis, except that ROH replaces HOH (by the acyl-oxygen fission mechanisms). When alkyl fission takes place, the products are the *acid* and the *ether*:



Therefore, transesterification reactions frequently fail when R′ is tertiary, since this type of substrate most often reacts by alkyl–oxygen cleavage. In such cases, the reaction is of the Williamson type with OCOR as the leaving group (see **10-10**).

102

With enol esters such as **102**, reaction with an alcohol gives an ester and the enol of a ketone, which readily tautomerizes to the ketone as shown. Hence, enol esters are good acylating agents for alcohols.[1694] This transformation has been

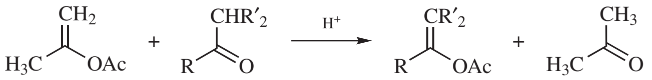
accomplished in ionic liquid media,[1695] and there is a $PdCl_2/CuCl_2$ mediated version.[1696] Isopropenyl acetate can also be used to convert other ketones to the corresponding enol acetates in an exchange reaction:[1697]



Enol esters can also be prepared in the opposite type of exchange reaction, catalyzed by mercuric acetate[1698] or Pd(II) chloride,[1699] for example,

$$\text{RCOOH} + \text{R}'\text{COOCH=CH}_2 \xrightleftharpoons[\text{H}_2\text{SO}_4]{\text{Hg(OAc)}_2} \text{RCOOCH=CH}_2 + \text{R}'\text{COOH}$$

A closely related reaction is equilibration of a dicarboxylic acid and its diester to produce monoesters: The reaction of a carboxylic acid with ethyl acetate, in the presence of $NaHSO_4$•SiO_2, was shown to give the corresponding ethyl ester.[1700] Iodine catalyzes the transesterification of β-keto esters.[1701]

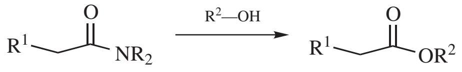
16-65 Alcoholysis of Amides

Alkoxy-de-amidation



Alcoholysis of amides is possible,[1702] although it is usually difficult. It has been most common with the imidazolide type of amides (e.g., **100**). For other amides, an activating agent is usually necessary before the alcohol will replace the NR_2 unit. Dimethylformamide, however, reacted with primary alcohols in the presence of 2,4,6-trichloro-1,3,5-pyrazine (cyanuric acid) to give the corresponding formate ester.[1703] Treatment of an amide with triflic anhydride ($CF_3SO_2OSO_2CF_3$) in the

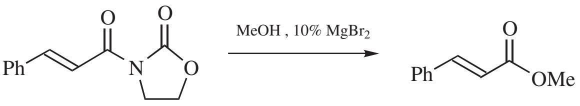
presence of pyridine and then with an excess of alcohol leads to the ester,[1704] as does treatment with $Me_2NCH(OMe)_2$ followed by the alcohol.[1705] Trimethyloxonium tetrafluoroborate converted primary amides to methyl esters.[1706] The reaction of acetanilide derivatives with sodium nitrite in the presence of acetic anhydride–acetic acid leads to phenolic acetates.[1707] Acyl hydrazides ($RCONHNH_2$) were converted to esters by reaction with alcohols and various reagents,[1708] and methoxyamides (RCONHOMe) were converted to esters with $TiCl_4$/ROH.[1709] The reaction of an oxazolidinone amide **103** with methanol and 10% $MgBr_2$ gave the corresponding methyl ester.[1710]



103

C. Attack by OCOR at an Acyl Carbon

16-66 Acylation of Carboxylic Acids With Acyl Halides

Acyloxy-de-halogenation

$$RCOCl \quad + \quad R'COO^- \longrightarrow RCOOCOR'$$

Unsymmetrical, as well as symmetrical, anhydrides are often prepared by the treatment of an acyl halide with a carboxylic acid salt. Cobalt(II) chloride ($CoCl_2$) has been used as a catalyst.[1711] If a metallic salt is used, Na^+, K^+, or Ag^+ are the most common cations, but more often pyridine or another tertiary amine is added to the free acid and the resulting salt is subsequently treated with the acyl halide. Mixed formic anhydrides are prepared from sodium formate and an aryl halide, by use of a solid-phase copolymer of pyridine-1-oxide.[1712] Symmetrical anhydrides can be prepared by reaction of the acyl halide with aq. NaOH or

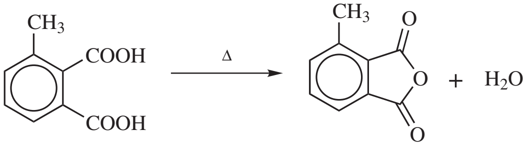
16-67 Acylation of Carboxylic Acids With Carboxylic Acids

Acyloxy-de-hydroxylation

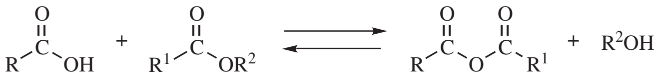
$$2\ RCOOH \xrightleftharpoons{P_2O_5} (RCO)_2O + H_2O$$

Anhydrides can be formed from two molecules of an ordinary carboxylic acid only if a dehydrating agent is present so that the equilibrium can be driven to the right. Common dehydrating agents[1715] are acetic anhydride, trifluoroacetic anhydride, dicyclohexylcarbodiimide,[1716] and P_2O_5. Triphenylphosphine/CCl_3CN with triethylamine has also been used with benzoic acid derivatives.[1717] The method is very poor for the formation of mixed anhydrides, which in any case generally undergo disproportionation to the two simple anhydrides when they are heated. However, simple heating of dicarboxylic acids does give cyclic anhydrides, provided that the ring formed contains five, six, or seven members, for example,



Malonic acid and its derivatives, which would give four-membered cyclic anhydrides, do not give this reaction when heated but undergo decarboxylation (**12-40**) instead.

Carboxylic acids exchange with amides and esters; these methods are sometimes used to prepare anhydrides if the equilibrium can be shifted, for example,



[1713]Plusquellec, D.; Roulleau, F.; Lefeuvre, M.; Brown, E. *Tetrahedron* ***1988***, *44*, 2471; Wang, J.; Hu, Y.; Cui, W. *J. Chem. Res. (S)* ***1990***, 84.

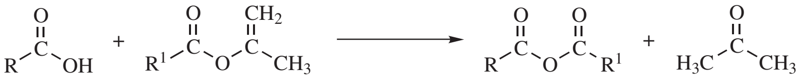
[1714]Hu, Y.; Wang, J.-X.; Li, S. *Synth. Commun.* ***1997***, *27*, 243.

[1715]For lists of other dehydrating agents with references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, ***1999***, pp. 1930–1932; Ogliaruso, M.A.; Wolfe, J.F., in Patai, S. *The Chemistry of Acid Derivatives*, pt.1, Wiley, NY, ***1979***, pp. 437–438.

[1716]For example, see Schüssler, H.; Zahn, H. *Chem. Ber.* ***1962***, *95*, 1076; Rammler, D.H.; Khorana, H.G. *J. Am. Chem. Soc.* ***1963***, *85*, 1997. See also, Hata, T.; Tajima, K.; Mukaiyama, T. *Bull. Chem. Soc. Jpn.* ***1968***, *41*, 2746.

[1717]Kim, J.; Jang, D.O. *Synth. Commun.* ***2001***, *31*, 395.

Enolic esters are especially good for this purpose, because the equilibrium is shifted by formation of the ketone.



The combination of KF with 2-acetoxypropene under microwave conditions was effective.[1718] Carboxylic acids also exchange with anhydrides; indeed, this is how acetic anhydride acts as a dehydrating agent in this reaction.

Anhydrides can be formed from certain carboxylic acid salts; for example, by treatment of trimethylammonium carboxylates with phosgene:[1719]

$$2\,RCO\overset{\ominus}{O}\;\;\overset{\oplus}{N}HEt_3 \xrightarrow{COCl_2} RCOOCOR \;+\; 2\,\overset{\oplus}{N}HEt_3\;\;Cl^{\ominus} \;+\; CO_2$$

or of thallium(I) carboxylates with thionyl chloride,[1605] or of sodium carboxylates with CCl_4 and a catalyst such as CuCl or $FeCl_2$.[1720]

16-68 Preparation of Mixed Organic–Inorganic Anhydrides

Nitrooxy-de-acyloxy-substitution

$$(RCO)_2O \;+\; HONO_2 \longrightarrow RCOONO_2$$

Mixed organic–inorganic anhydrides are seldom isolated, though they are often intermediates when acylation is carried out with acid derivatives catalyzed by inorganic acids. Sulfuric, perchloric, phosphoric, and other acids form similar anhydrides, most of which are unstable or not easily obtained because the equilibrium lies in the wrong direction. These intermediates are formed from amides, carboxylic acids, and esters, as well as anhydrides. Organic anhydrides of phosphoric acid are more stable than most others and, for example, $RCOOPO(OH)_2$ can be prepared in the form of its salts.[1721] Mixed anhydrides of carboxylic and sulfonic acids ($RCOOSO_2R'$) are obtained in high yields by treatment of sulfonic acids with acyl halides or (less preferred) anhydrides.[1722]

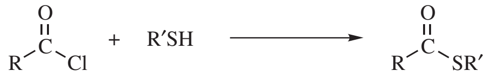
16-69 Attack by SH or SR at an Acyl Carbon[1723]

Mercapto-de-halogenation



Alkylthio-de-halogenation

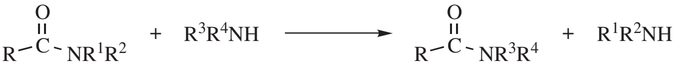
Thiol acids and thiol esters[1724] can be prepared in this manner, which is analogous to **16-57** and **16-64**. Anhydrides[1725] and aryl esters (RCOOAr)[1726] are also used as substrates, but the reagents in these cases are usually HS^- and RS^-. Thiol esters can also be prepared by treatment of carboxylic acids with P_4S_{10}—Ph_3SbO,[1727] or with a thiol RSH and either polyphosphate ester or phenyl dichlorophosphate $PhOPOCl_2$.[1728] Esters RCOOR′ can be converted to thiol esters $RCOSR^2$ by treatment with trimethylsilyl sulfides Me_3SiSR^2 and $AlCl_3$.[1729]

Alcohols, when treated with a thiol acid and zinc iodide, give thiol esters (R′COSR)[1730]

OS **III**, 116, 599; **IV**, 924, 928; **VII**, 81; **VIII**, 71.

16-70 Transamidation

Alkylamino-de-amidation



It is sometimes necessary to replace one amide group with another, particularly when the group attached to nitrogen functions as a protecting group[1731] *N*-Benzyl amides can be converted to the corresponding *N*-allyl amide with allylamine and titanium catalysts.[1732] Reaction of *N*-Boc 2-phenylethylamine (Boc = *tert*-butoxy carbonyl) with $Ti(OiPr)_4$ and benzyl alcohol, for example, gives the *N*-Cbz derivative (Cbz = carbobenzoylcarbonyl).[1733] *N*-Carbamoyl amines were converted to

16-72 Acylation of Amines by Acyl Halides

Amino-de-halogenation

$$\text{RCOX} + \text{NH}_3 \longrightarrow \text{RCONH}_2 + \text{HX}$$

The treatment of acyl halides with ammonia or amines is a very general reaction for the preparation of amides.[1745] The reaction is highly exothermic and must be carefully controlled, usually by cooling or dilution. Ammonia gives unsubstituted amides, primary amines give *N*-substituted amides,[1746] and secondary amines give *N,N*-disubstituted amides. Arylamines can be similarly acylated. Hydroxamic acids have been prepared by this route.[1747] In some cases, aqueous alkali is added to combine with the liberated HCl. This is called the *Schotten–Baumann procedure*, as in **16-61**. Activated zinc can be used to increase the rate of amide formation when hindered amines and/or acid chlorides are used.[1748] An indium-mediated amidation reaction[1749] and a BiOCl-mediated reaction[1750] have been reported. A variation of this basic reaction uses DMF with acyl halides to give *N,N*-dimethylamides.[1751] A solvent-free reaction was reported using DABCO and methanol.[1752]

Hydrazine and hydroxylamine also react with acyl halides to give, respectively, hydrazides ($RCONHNH_2$)[1753] and hydroxamic acids (RCONHOH).[1754] When phosgene is the acyl halide, both aliphatic and aromatic primary amines give chloroformamides (ClCONHR) that lose HCl to give isocyanates (RNCO).[1755] This is one of the most common methods for

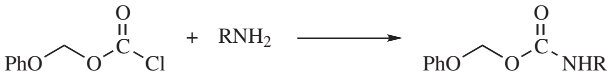
[1755]For reviews of the preparation and reactions of isocyanates and isothiocyanates, see, respectively, the articles by Richter, R.; Ulrich, H. pp. 619–818, and Drobnica, L.; Kristián, P.; Augustín, J. pp. 1003–1221, in Patai S. *The Chemistry of Cyanates and Their Thio Derivatives*, pt. 2, Wiley, NY, ***1977***.

the preparation of isocyanates.[1756] Thiophosgene,[1757] similarly treated, gives isothiocyanates. A safer substitute for phosgene in this reaction is trichloromethyl chloroformate CCl_3OCOCl.[1758] When chloroformates ROCOCl are treated with primary amines, carbamates ROCONHR′ are obtained.[1759] An example of this reaction is the use of benzyl chloroformate to protect the amino group of amino acids and peptides.



107

The $PhCH_2OCO$ group in **107** is called the carbobenzoxy group,[1760] and is often abbreviated Cbz or Z. Another important group similarly used is the *tert*-butoxycarbonyl group Me_3COCO, abbreviated as Boc. In this case, the chloride ($Me_3COCOCl$) is unstable, so the anhydride, $(Me_3COCO)_2O$, is used instead, in an example of **16-73**. Amino groups in general are often protected by conversion to amides.[1761] The treatment of acyl halides with lithium nitride gives *N,N*-diacyl amides (triacylamines), **108**.[1762] The reactions proceed by the tetrahedral mechanism.[1763]

$$3\,RCOCl \;+\; Li_3N \longrightarrow (RCO)_3N$$

108

A novel variation of this reaction uses nitrogen gas as the nitrogen source in the amide. The reaction of benzoyl chloride with $TiCl_4/Li/Me_3SiCl/CsF$ and N_2, gave a 77% yield of benzamide.[1764]

An interesting variation of this transformation reacts carbamoyl chlorides with organocuprates to give the corresponding amide.[1765]

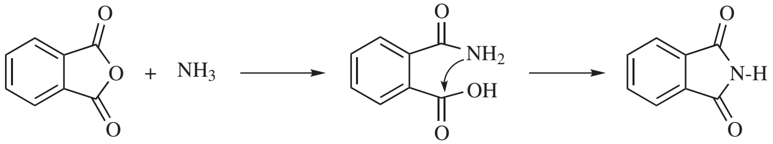
16-73 Acylation of Amines by Anhydrides

Amino-de-acyloxy-substitution

This reaction, similar in scope and mechanism[1766] to **16-72**, can be carried out with ammonia or primary or secondary amines.[1767] Note that there is a report where a tertiary amine (an *N*-alkylpyrrolidine) reacted with acetic anhydride at 120°C, in the presence of a BF_3•etherate catalyst, to give *N*-acetylpyrrolidine (an acylative dealkylation).[1768] Amino acids can be *N*-acylated using acetic anhydride and ultrasound.[1769] However, ammonia and primary amines can also give imides, in which two acyl groups are attached to the nitrogen. The conversion of cyclic anhydrides to cyclic imides is generally facile,[1770] although elevated temperatures are occasionally required to generate the imide.[1771] Microwave irradiation of formamide and a cyclic anhydride generates the cyclic imide.[1772] Cyclic imides have also been formed in ionic liquids.[1773] Cyclic imides were also formed by microwave irradiation of a polymer-bound phthalate after initial reaction with an amine.[1774]



The second step for imide formation, which is much slower than the first, is the attack of the amide nitrogen on the carboxylic carbon. Unsubstituted and *N*-substituted amides have been used instead of ammonia. Since the other product

of this reaction is RCOOH, this is a way of "hydrolyzing" such amides in the absence of water.[1775]

Even though formic anhydride is not a stable compound (see p. 723), amines can be formylated with the mixed anhydride of acetic and formic acids (HCOO-COMe)[1776] or with a mixture of formic acid and acetic anhydride. Acetamides are not formed with these reagents. Secondary amines can be acylated in the presence of a primary amine by conversion to their salts and addition of 18-crown-6.[1777] The crown ether complexes the primary ammonium salt, preventing its acylation, while the secondary ammonium salts, which do not fit easily into the cavity, are free to be acylated. Dimethyl carbonate can be used to prepare methyl carbamates in a related procedure.[1778] *N*-Acetylsulfonamides were prepared from acetic anhydride and a primary sulfonamide, catalyzed by Montmorillonite K10–FeO[1779] or sulfuric acid.[1780]

The reaction of anhydrides with aryl azides, in the presence of Me_3SiCl and NaI, gives *N*-aryl imides.[1781]

16-74 Acylation of Amines by Carboxylic Acids

Amino-de-hydroxylation

$$RCOOH + NH_3 \longrightarrow RCOO^-NH_4^+ \xrightarrow{\text{pyrolysis}} RCONH_2$$

When carboxylic acids are treated with ammonia or amines, salts are obtained. The salts of ammonia or primary or secondary amines can be pyrolyzed to give amides,[1782] but the method is less convenient than **16-72**, **16-73**, and **16-75** and is seldom of preparative value.[1783] Heating in the presence of a base such as hexamethyldisilazide makes the amide-forming process more efficient.[1784] Boronic acids catalyze the direct conversion of carboxylic acid and amine to amides.[1785]

Polymer-bound reagents have also been used.[1786] The synthetically important Weinreb amides [RCON(Me)OMe, see **16-82**] can be prepared from the carboxylic acid and MeO(Me)NH•HCl in the presence of tributylphosphine and 2-pyridine-*N*-oxide disulfide.[1787] Di(2-pyridyl)carbonate has been used in a related reaction that generates amides directly.[1788] The reaction of a carboxylic acid and imidazole under microwave irradiation gives the amide.[1789] Microwave irradiation of a secondary amine, formic acid, 2-chloro-4,6-dimethoxy[1,3,5]triazine, and a catalytic amount of DMAP (4-dimethylaminopyridine) leads to the formamide.[1790] Ammonium bicarbonate and formamide converts acids to amides with microwave irradiation.[1791] Lactams are readily produced from γ- or δ-amino acids,[1792] for example,

This lactamization process can be promoted by enzymes, such as pancreatic porcine lipase.[1793] Reduction of ω-azido carboxylic acids leads to macrocyclic lactams.[1794]

Although treatment of carboxylic acids with amines does not directly give amides, the reaction can be made to proceed in good yield at room temperature or slightly above by the use of coupling agents,[1795] the most important of which is dicyclohexylcarbodiimide. This reagent is very convenient and is used[1796] a great deal in peptide synthesis.[1797] A polymer-supported carbodiimide has been used.[1798] The mechanism is probably the same as in **16-63** up to the formation

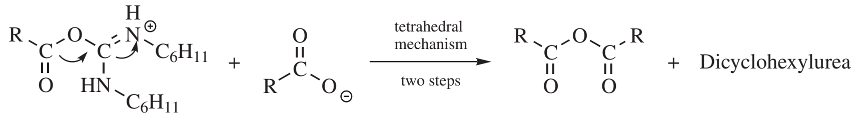
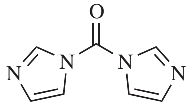
of **109**. This intermediate is then attacked by another molecule of $RCOO^-$ to give the anhydride $(RCO)_2O$, which is the actual species that reacts with the amine:



109

The anhydride has been isolated from the reaction mixture and then used to acylate an amine.[1799] Other promoting agents[1800] are $ArB(OH)_2$ reagents,[1801] $Sn[N(TMS)_2]_2$,[1802] *N,N′*-carbonyldiimidazole (**110**, p. 1418),[1803] which behaves as in reaction **16-63**, $POCl_3$,[1804] $TiCl_4$,[1805] molecular sieves,[1806] Lawesson's reagent (p. 1278),[1807] and $(MeO)_2POCl$.[1808] Certain dicarboxylic acids form amides simply on treatment with primary aromatic amines. In these cases, the cyclic anhydride is an intermediate and is the species actually attacked by the amine.[1809] Carboxylic acids can also be converted to amides by heating with amides of carboxylic acids (exchange),[1810] sulfonic acids, or phosphoric acids, for example,[1811]



110

or by treatment with trisalkylaminoboranes, $B(NHR')_3$, with trisdialkylaminoboranes, $B(NR'_2)_3$,[1812]

$$RCOOH \quad + \quad B(NR_2')_3 \longrightarrow RCONR_2'$$

or with bis(diorganoamino)magnesium reagents $(R_2N)_2Mg$.[1813] The reaction of thiocarboxylic acids and azides, in the presence of triphenylphosphine, gives the corresponding amide.[1814]

An important technique, discovered by R.B. Merrifield in 1963[1815] and since used for the synthesis of many peptides,[1816] is called *solid phase synthesis* or *polymer-supported synthesis*.[1817] The reactions used are the same as in ordinary synthesis, but one of the reactants is anchored onto a solid polymer. For example, if it is desired to couple two amino acids (to form a dipeptide), the polymer selected might be polystyrene with CH_2Cl side chains. One of the amino acids, protected by a *tert*-butoxycarbonyl group (Boc), would then be coupled to the side chains. It is not necessary that all the side chains be converted, but a random selection will be. The Boc group is then removed by hydrolysis with trifluoroacetic acid in CH_2Cl_2 and the second amino acid is coupled to the first, using DCC or some other coupling agent. The second Boc group is removed, resulting in a dipeptide that is still anchored to the polymer. If this dipeptide is the desired product, it can be cleaved from the polymer by various methods,[1818] one of which is treatment with HF. If a longer peptide is wanted, additional amino acids can be added by repeating the requisite steps.

[1818]For some of these methods, see Whitney, D.B.; Tam, J.P.; Merrifield, R.B. *Tetrahedron* ***1984***, *40*, 4237.

The basic advantage of the polymer-support techniques is that the polymer (including all chains attached to it) is easily separated from all other reagents, because it is insoluble in the solvents used. Excess reagents, other reaction products (e.g., dicyclohexylurea), side products, and the solvents themselves are quickly washed away. Purification of the polymeric species is rapid and complete. The process can even be automated,[1819] to the extent that six or more amino acids can be added to a peptide chain in one day. Commercial automated peptide synthesizers are now available.[1820]

Although the solid-phase technique was first developed for the synthesis of peptide chains and has seen considerable use for this purpose, it has also been used to synthesize chains of polysaccharides and polynucleotides; in the latter case, solid-phase synthesis has almost completely replaced synthesis in solution.[1821] The technique has been applied less often to reactions in which only two molecules are brought together (nonrepetitive syntheses), but many examples have been reported.[1822] Combinatorial chemistry had its beginning with the Merrifield synthesis, particularly when applied to peptide synthesis, and continues as an important part of modern organic chemistry.[1823]

16-75 Acylation of Amines by Carboxylic Esters

Amino-de-alkoxylation

$$RCOOR' + NH_3 \longrightarrow RCONH_2 + R'OH$$

The conversion of carboxylic esters to amides is a useful reaction, and unsubstituted, *N*-substituted, and *N,N*-disubstituted amides can be prepared this way from the appropriate amine.[1824] Both R and R′ can be alkyl or aryl, but an especially

good leaving group is *p*-nitrophenyl. Ethyl trifluoroacetate was found to react selectively with primary amines to form the corresponding trifluoroacetyl amide.[1825] Many simple esters (R = Me, Et, etc.) are not very reactive, and strongly basic catalysis has been used in such cases,[1826] but catalysis by cyanide ion[1827] $MgBr_2$,[1828] InI_3,[1829] and acceleration by high pressure[1830] have been reported. Methyl esters have been converted to the corresponding amide under microwave irradiation,[1831] and also ethyl esters.[1832] Lithium amides have been used to convert esters to amides as well.[1833] β-Keto esters undergo the reaction especially easily.[1834] In another procedure, esters are treated with dimethylaluminum amides (Me_2AlNRR') to give good yields of amides under mild conditions.[1835] The reagents are easily prepared from Me_3Al and NH_3 or a primary or secondary amine or their salts. This is particularly effective when a reactive substituent, such as a primary halide, is present elsewhere in the molecule.[1836] Tin reagents, such as $Sn[N(TMS)_2]_2$, in the presence of an amine can also be use to convert an ester to an amide.[1837] This reagent can also be used to convert β-amino esters to β-lactams.[1838] Aniline was treated with *n*-butyllithium to form the lithium amide, which reacted with an ester to give the amide.[1839] The ester-to-amide conversion has also been accomplished electrochemically, by passing electric current in the cathodic compartment.[1840] An enzyme-mediated amidation is known using amino cyclase I.[1841] The reaction of dimethyl carbonate and an amine is an effective way to prepare methyl carbamates.[1842]

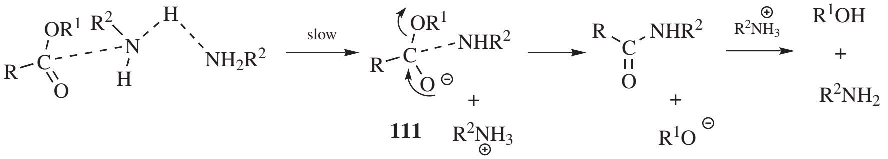
As in **16-72**, hydrazides and hydroxamic acids can be prepared from carboxylic esters, with hydrazine and hydroxylamine, respectively. Both hydrazine and hydroxylamine react more rapidly than ammonia or primary amines (the alpha effect, p. 495). Imidates RC(=NH)OR′ give amidines $RC(=NH)NH_2$. Lactones, when treated with ammonia or primary amines, give lactams. Lactams are also produced from γ- and δ-amino esters in an internal example of this reaction. Isopropenyl formate is a useful compound for the formylation of primary and secondary amines.[1843]

$$R_2NH + HCOOCMe = CH_2 \longrightarrow R_2NCHO + CH_2 = CMeOH \longrightarrow MeCOMe$$

Although more studies have been devoted to the mechanism of the acylation of amines with carboxylic esters than with other reagents, the mechanistic details are not yet entirely clear.[1844] In its broad outlines, the mechanism appears to be essentially $B_{AC}2$.[1845] Under the normal basic conditions, the reaction is general base-catalyzed,[1846] indicating that a proton is being transferred in the rate-determining step and that two molecules of amine are involved.[1847]



Alternatively, another base, such as H_2O or OH^-, can substitute for the second molecule of amine. With some substrates and under some conditions, especially at low pH, the breakdown of **111** can become rate determining.[1848] The reaction also takes place under acidic conditions and is general acid catalyzed, so that

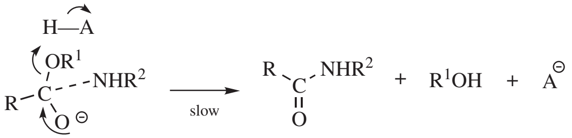
breakdown of **111** is rate determining and proceeds as follows:[1849]



111

HA may be $R^2NH_3^+$ or another acid. Intermediate **111** may or may not be further protonated on the nitrogen. Even under basic conditions, a proton donor may be necessary to assist leaving-group removal. Evidence for this is that the rate is lower with NR_2^- in liquid ammonia than with NHR_2 in water, apparently owing to the lack of acids to protonate the leaving oxygen.[1850]

In the special case of β-lactones, where small-angle strain is an important factor, alkyl–oxygen cleavage is observed ($B_{AL}2$ mechanism, as in the similar case of hydrolysis of β-lactones, **16-59**), and the product is not an amide but a β-amino acid (β-alanine).

β-Alanine

A similar result has been found for certain sterically hindered esters.[1851] This reaction is similar to **10-31**, with OCOR as the leaving group. Other lactones have been opened to ω-hydroxy amides with Dibal:$BnNH_2$.[1852]

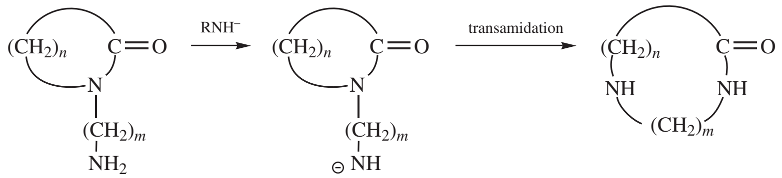
amines (in the form of their salts) are the most common reagents. Boron trifluoride can be added to complex with the leaving ammonia. Neutral amines also react in some cases to give the new amide.[1854] The reaction is often used to convert urea to substituted ureas: $NH_2CONH_2 + RNH_3^+ \rightarrow NH_2CONHR + NH_4^+$.[1855] An *N*-aryl group of a urea can be converted to a *N,N*-dialkyl group by heating the urea with the amine in an autoclave.[1856] *N*-R-Substituted amides are converted to *N*-R′-substituted amides by treatment with N_2O_4 to give an *N*-nitroso compound, followed by treatment of this with a primary amine $R'NH_2$.[1857] Lactams can be converted to ring-expanded lactams if



a side chain containing an amino group is present on the nitrogen. A strong base is used to convert the NH_2 to NH^-, which then acts as a nucleophile, expanding the ring by means of a transamidation.[1858] The discoverers call it the *Zip reaction*, by analogy with the action of zippers.[1859]

Lactams can be opened to ω-amino amides by reaction with amines at 10 kbar.[1860]

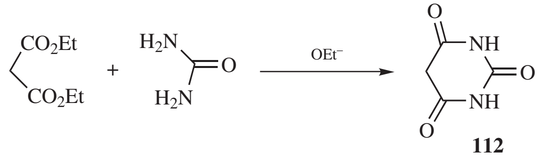
[1862]The best results are obtained when the acyloxyboranes are made from a carboxylic acid and catecholborane (p. 1123): Collum, D.B.; Chen, S.; Ganem, B. *J. Org. Chem.* ***1978***, *43*, 4393.

1,1,1-trihalo ketones $RCOCX_3$,[1863] α-keto nitriles, acyl azides, and non-enolizable ketones (see the Haller–Bauer reaction **12-34**). A polymer-bound acyl derivative was converted to an amide using tributylvinyl tin, trifluoroacetic acid, $AsPh_3$ and a palladium catalyst.[1864] The source of amine in this reaction was the polymer itself, which was an amide resin. *N*-Acylsulfonamides react with primary amines to the amide (AcNHR).[1865] Aniline derivatives are converted to acetamides with *N*-acyl oxymethylpyradazin-3-ones in dichloromethane.[1866] Carbonylation reactions can be used to prepare amides and related compounds. The reaction of a primary amine, an alkyl halide with CO_2, in the presence of Cs_2CO_3/Bu_4NI, gave the corresponding carbamate.[1867]

OS **III**, 394; **IV**, 6, 569; **V**, 160, 166; **VI**, 1004.

Imides can be prepared by the attack of amides or their salts on acyl halides, anhydrides, and carboxylic acids or esters.[1868] The best synthetic method for the preparation of acyclic imides is the reaction between an amide and an anhydride at 100°C catalyzed by H_2SO_4.[1869] When acyl chlorides are treated with amides in a 2:1 molar ratio at low temperatures in the presence of pyridine, the products are *N,N*-diacylamides, $(RCO)_3N$.[1870]

This reaction is often used to prepare urea derivatives, an important example being the preparation of barbituric acid, **112**.[1871]



112

When the substrate is oxalyl chloride (ClCOCOCl) and the reagent an unsubstituted amide, an acyl isocyanate (RCONCO) is formed. The "normal" product (RCONH-COCOCl) does not form, or if it does, it rapidly loses CO and HCl.[1872]

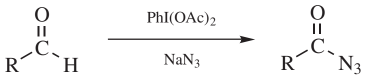
16-78 Acylation of Azides



The reaction of an aldehyde with sodium azide and Et_4 $I(OAc)_2$ or polymer-bound $PhI(OAc)_2$ leads to an acyl azide.[1873]

F. Attack by Halogen at an Acyl Carbon

16-79 Formation of Acyl Halides from Carboxylic Acids

Halo-de-hydroxylation

$$\text{RCOOH} + \underset{\text{agent}}{\text{Halogenating}} \longrightarrow \text{RCOX}$$

Halogenating agent = $SOCl_2$, $SOBr_2$, PCl_3, $POCl_3$, PBr_3, and so on.

The same inorganic acid halides that convert alcohols to alkyl halides (**10-48**) also convert carboxylic acids to acyl halides.[1874] The reaction is the best and the most common method for the preparation of acyl chlorides. Bromides and iodides[1875] are also made in this manner, but much less often. Acyl bromides can be prepared with BBr_3 on alumina.[1876] Thionyl chloride[1877] is a good reagent, since the by-products are gases and the acyl halide is easily isolated, but PX_3 and PX_5 (X = Cl or Br) are also commonly used.[1878] Hydrogen halides do not give the reaction. A particularly mild procedure, similar to one mentioned in **10-48**, involves reaction of the acid with Ph_3P in CCl_4, whereupon acyl chlorides are produced without obtaining any acidic compound as a by-product.[1879] Acyl fluorides can be prepared by treatment of carboxylic acids with cyanuric fluoride.[1880] Acid salts

are also sometimes used as substrates. Acyl halides are also used as reagents in an exchange reaction:

$$\text{RCOOH} + \text{R'COCl} \rightleftharpoons \text{RCOCl} + \text{R'COOH}$$

which probably involves an anhydride intermediate. This is an equilibrium reaction that must be driven to the desired side.

A mild, and often superior reagent is oxalyl chloride (**113**) and oxalyl bromide, since oxalic acid decomposes to CO and CO_2, and the equilibrium is thus driven to the side of the other acyl halide.[1881] These reagents are commonly the reagent of choice, particularly when sensitive functionality is present elsewhere in the molecule.

$$(\text{RCO})_2\text{O} + \text{HF} \longrightarrow \text{RCOF}$$
$$\text{RCOCl} + \text{HF} \longrightarrow \text{RCOF}$$

These reactions are most important for the preparation of acyl fluorides.[1882] Acyl chlorides and anhydrides can be converted to acyl fluorides by treatment with polyhydrogen fluoride–pyridine solution[1883] or with liquid HF at $-10°C$.[1884] Formyl fluoride, which is a stable compound, was prepared by the latter procedure from the mixed anhydride of formic and acetic acids.[1885] Acyl fluorides can also be obtained by reaction of acyl chlorides with KF in acetic acid[1886] or with diethylaminosulfur trifluoride (DAST).[1887] Carboxylic esters and anhydrides can be

converted to acyl halides other than fluorides by the inorganic acid halides mentioned in **16-79**, as well as with Ph_3PX_2 (X = Cl or Br),[1888] but this is seldom done. Halide exchange can be carried out in a similar manner. When halide exchange is done, it is always acyl bromides and iodides that are made from chlorides, since chlorides are by far the most readily available.[1889]

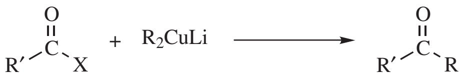
G. Attack by Carbon at an Acyl Carbon[1890]

16-81 The Conversion of Acyl Halides to Ketones With Organometallic Compounds[1891]

Alkyl-de-halogenation



Acyl halides react cleanly and under mild conditions with lithium dialkylcopper reagents (see **10-58**)[1892] to give high yields of ketones.[1893] The R′ group may be primary, secondary, or tertiary alkyl or aryl and may contain iodo, keto, ester, nitro, or cyano groups. The R groups that have been used successfully are methyl, primary alkyl, and vinylic. Secondary and tertiary alkyl groups can be introduced by the use of PhS(R)CuLi (p. 602) instead of R_2CuLi,[1894] or by the use of either the mixed homocuprate $(R'SO_2CH_2CuR)^-\ Li^+$,[1895] or a magnesium dialkylcopper reagent "RMeCuMgX."[1896] Secondary alkyl groups can also be introduced with the copper–zinc reagents RCu(CN)ZnI.[1897] The R group may be alkynyl if a

cuprous acetylide $R^2C{\equiv}CCu$ is the reagent.[1898] Organocopper reagents generated *in situ* from highly reactive copper, and containing such functional groups as cyano, chloro, and ester, react with acyl halides to give ketones.[1899]

Many other organometallic reagents[1900] give good yields of ketones when treated with acyl halides because, as with R_2CuLi, R_2Cd, these compounds do not generally react with the ketone product. A particularly useful class of organometallic reagent are organocadmium reagents R_2Cd, prepared from Grignard reagents (**12-22**). In this case, R may be aryl or primary alkyl. In general, secondary and tertiary alkylcadmium reagents are not stable enough to be useful in this reaction.[1901] An ester group may be present in either R′COX or R_2Cd. Direct treatment of the acid chloride with an alkyl halide and cadmium metal leads to the ketone in some cases.[1902] Organozinc compounds behave similarly to dialkylcadmium reagents, but are used less often.[1903] Organotin reagents R_4Sn react with acyl halides to give high yields of ketones, if a Pd complex is present.[1904] Organolead reagents R_4Pb behave similarly.[1905] Allylic halides and indium metal react with acyl chlorides to give the ketone.[1906] Various other groups, for example, nitrile, ester, and aldehyde can be present in the acyl halide without interference. Other reagents include organomanganese compounds[1907] (R can be primary, secondary, or tertiary alkyl, vinylic, alkynyl, or aryl), organozinc,[1908] and organothallium compounds (R can be primary alkyl or aryl).[1909] The reaction of an α-halo-ketone and an acyl chloride with SmI_2 leads to a β-diketone.[1910] Initial reaction of an acyl chloride with palladium(0), followed by reaction with potassium acetate and then a trialkylborane gave a ketone.[1911] Arylboronic acids and acid chloride give the ketone in

the presence of a palladium catalyst.[1912] Similar reaction of acid chlorides, $NaBPh_4$, KF, and a palladium catalyst gave the aryl ketone.[1913] Antimony alkynes such as Ph_2Sb—C≡C—Ph react with acid chloride in the presence of a palladium catalyst to give the conjugated alkynyl ketone.[1914] Such conjugated ketones can also be prepared from an acyl halide, a terminal alkyne and a CuI catalyst[1915] a palladium catalyst,[1916] or with indium metal.[1917] Terminal alkynes react with chloroformates and a palladium catalyst to give the corresponding propargyl ester.[1918] Similar reaction of an alkyne with an acid chloride and a palladium–copper[1919] or CuI catalyst,[1920] both with microwave irradiation, gave the alkynyl ketones.

When the organometallic compound is a Grignard reagent,[1921] ketones are generally not obtained because the initially formed ketone reacts with a second molecule of RMgX to give the salt of a tertiary alcohol (**16-82**). Ketones *have* been prepared in this manner by the use of low temperatures, inverse addition (i.e., addition of the Grignard reagent to the acyl halide rather than the other way), excess acyl halide, and so on., but the yields are usually low, though high yields have been reported in THF at −78°C.[1922] Pretreatment with a trialkylphosphine and then the Grignard reagent can lead to the ketone.[1923] Using CuBr[1924] or a nickel catalyst[1925] with the Grignard reagent can lead to the ketone. Some ketones are unreactive toward Grignard reagents for steric or other reasons; these can be prepared in this way.[1926] Other methods involve running the reaction in the presence of Me_3SiCl[1927] (which reacts with the initial adduct in the tetrahedral mechanism, p. 1254), and the use of a combined Grignard-lithium diethylamide reagent.[1928] Also, certain metallic halides, notably ferric and cuprous halides, are catalysts

that improve the yields of ketone at the expense of tertiary alcohol.[1929] For these catalysis, both free radical and ionic mechanisms have been proposed.[1930]

Grignard reagents react with ethyl chloroformate to give carboxylic esters $EtOCOCl + RMgX \rightarrow EtOCOR$. Acyl halides can also be converted to ketones by treatment with $Na_2Fe(CO)_4$ followed by R′X (**10-76**).

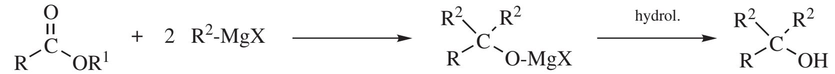
16-82 The Conversion of Anhydrides, Carboxylic Esters, or Amides to Ketones With Organometallic Compounds[1931]

Dialkyl,hydroxy-de-alkoxy,oxo-tersubstitution; Alkyl-de-acyloxy- or de-amido substitution



When carboxylic esters are treated with Grignard reagents, addition to the carbonyl (**16-24**) generates a ketone. Under the reaction conditions, the initially formed ketones usually undergoes acyl substitution of R^2 for OR′ (**16-81**), so that tertiary alcohols are formed in which two R groups are the same. Isolation of the ketone as the major product is possible in some cases, particularly when the reaction is done at low temperature[1932] and when there is steric hindrance to the carbonyl in the first-formed ketone. Esters, RCO_2Me, react with $Zn(BH_4)_2$/EtMgBr to give an alcohol, RCH(OH)Et.[1933] Formates give secondary alcohols and carbonates give tertiary alcohols in which all three R groups are the same: $(EtO)_2C{=}O + RMgX \rightarrow R_3COMgX$. Acyl halides and anhydrides behave similarly, though these substrates are employed less often.[1934] Many side reactions are possible, especially when the acid derivative or the Grignard reagent is branched: enolizations, reductions (not for esters, but for halides), condensations, and cleavages, but the most important is simple substitution (**16-81**), which in some cases can be made to predominate. When 1,4-dimagnesium compounds are used, carboxylic esters are converted to cyclopentanols.[1935] 1,5-Dimagnesium

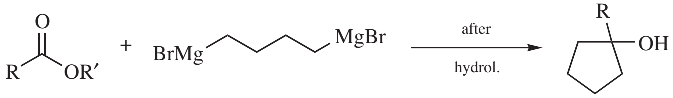
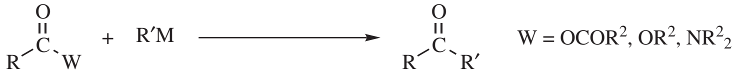
compounds give cyclohexanols, but in lower yields.[1936]



As is the case with acyl halides (**16-81**), anhydrides and carboxylic esters give tertiary alcohols (**16-82**) when treated with Grignard reagents. Low temperatures,[1937] the solvent HMPA,[1938] and inverse addition have been used to increase the yields of ketone.[1939] Amides give better yields of ketone at room temperature, but still not very high.[1940] Anhydrides can react with arylmagnesium halides at low temperature, and in the presence of (−)-sparteine, to give a keto acid with good enantioselectivity.[1941] Organocadmium reagents are less successful with these substrates than with acyl halides (**16-81**). Esters of formic acid, dialkylformamides, and lithium or sodium formate[1942] give good yields of aldehydes, when treated with Grignard reagents.



Alkyllithium compounds have been used to give ketones from carboxylic esters. The reaction must be carried out in a high-boiling solvent, such as toluene, since reaction at lower temperatures gives tertiary alcohols.[1943] Alkyllithium reagents also give good yields of carbonyl compounds with *N*,*N*-disubstituted amides.[1944] Dialkylformamides give aldehydes and other disubstituted amides give ketones and other acid derivatives have been used.[1945]

Ketones can also be obtained by treatment of the lithium salt of a carboxylic acid with an alkyllithium reagent (**16-28**). For an indirect way to convert carboxylic esters to ketones, see **16-82**. A similar reaction with hindered aryl carboxylic acids has been reported.[1946] Treatment of a β-amido acid with two equivalents of *n*-butyllithium, followed by reaction with an acid chloride leads to a β-keto amide.[1947] Carboxylic acids can be treated with 2-chloro-4,6-dimethoxy[1,3,5]-triazine and the RMgX/CuI to give ketones.[1948]

Disubstituted formamides can give addition of 2 equivalents of Grignard reagent. The products of this reaction (called *Bouveault reaction*) are an aldehyde and a tertiary amine.[1949] The use of an amide other than a formamide

can give a ketone instead of an aldehyde, but yields are generally low. The addition of 2 equivalents of phenyllithium to a carbamate gave good yields of the ketone, however.[1950] When butyllithium reacted with an α-carbamoyl secondary amide [$RCH(NHCO_2R')C(=O)NR^2_2$] at −78°C, the amide reacted preferentially to give the α-carbamoyl ketone.[1951] The reaction of *N*-(3-bromopropyl) lactams with *tert*-butyllithium gave cyclization to the bicyclic amino alcohol, and subsequent reduction with $LiAlH_4$ (**19-64**) gave the bicyclic amine.[1952] Ketones can also be prepared by treatment of thioamides with organolithium compounds (alkyl or aryl).[1953] Cerium reagents, such as $MeCeCl_2$, also add two R groups to an amide.[1954] More commonly, an organolithium reagent is treated with $CeCl_3$ to generate the organocerium reagent *in situ*.[1955] It has proven possible to add two different R groups by sequential addition of two Grignard reagents.[1956] Diketones have also been produced by using the bis(imidazole) derivative of oxalic acid.[1957] Alternatively, if R′ contains an α hydrogen, the product may be an enamine, and enamines have been synthesized in goods yields by this method.[1958] When an amide having a *gem*-dibromocyclopropyl unit elsewhere in the molecule was treated

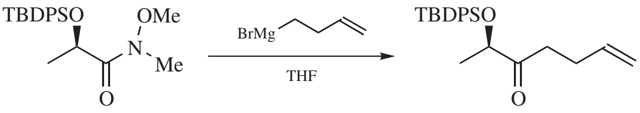
with methyllithium, Li—Br exchange was accompanied by intramolecular acyl addition to the amide carbonyl, giving a bicyclic amino alcohol.[1959]

N-Methoxy-*N*-methyl amides, such as, **114**, are referred to as a **Weinreb amide**.[1960] When a Weinreb amide reacts with a Grignard reagent or an organolithium reagent,[1961] the product is the ketone. The reaction of **56** with 3-butenylmagnesium bromide to give ketone **115** is a typical example.[1962] Aryloxy carbamates with a Weinreb amide unit, ArO_2C—NMe(OMe), react with RMgBr and then R′Li to give an unsymmetrical ketone, RC(=O)R′.[1963] Intramolecular displacement of a Weinreb amide by an organolithium reagent generated *in situ* from an iodide precursor leads to cyclic ketones.[1964] Reaction with vinylmagnesium bromide led to a β-*N*-methoxy-*N*-methylamino ketone, presumably by initial formation of the conjugated ketone followed by Michael addition (**15-24**) of the liberated amine.[1965] An interesting extension of this acyl substitution reaction coupled vinylmagnesium bromide with a Weinreb amide to give a conjugated ketone, which reacted with a secondary amine in a second step (see **15-31**) to give a β-amino ketone.[1966]



114 **115**

By the use of the compound *N*-methoxy-*N*,*N*′,*N*′-trimethylurea, it is possible to add two R groups as RLi, the same or different, to a CO group.[1967]

N,*N*-Disubstituted amides can be converted to alkynyl ketones by treatment with alkynylboranes: $RCONR^2_2 + (R'C{\equiv}C)_3B \rightarrow RCOC{\equiv}CR'$.[1968] Lactams react with triallylborane to give cyclic 2,2-diallyl amines after treatment with methanol, and then aqueous hydroxide.[1969] Triallylborane reacts with the carbonyl group of lactams, and after treatment with methanol and then aqueous NaOH gives the

gem-diallyl amine: 2-pyrrolidinone → 2,2-diallylpyrrolidine.[1970] *N*,*N*-Disubstituted carbamates ($X = OR^2$) and carbamoyl chlorides (X = Cl) react with 2 equivalents of an alkyl- or aryllithium or Grignard reagent to give symmetrical ketones, in which both R groups are derived from the organometallic compound: $R'_2NCOX + 2\,RMgX \rightarrow R_2CO$.[1971] *N*,*N*-Disubstituted amides give ketones in high yields when treated with alkyllanthanum triflates $RLa(OTf)_2$.[1972]

Other organometallic reagents give acyl substitution. Sodium naphthalenide reacts with esters to give naphthyl ketones.[1973] Trimethylaluminum, which exhaustively methylates ketones (**16-24**), also exhaustively methylates carboxylic acids to give *tert*-butyl compounds[1974] (see also, **10-63**). Trimethylaluminum reacts with esters to form ketones, in the presence of *N*,*N*′-dimethylethyelnediamine.[1975] Thioesters (RCOSR′) react with arylboronic acids, in the presence of a palladium catalyst, to give the corresponding ketone,[1976] and esters react similarly with arylboronic acids (a palladium catalyst)[1977] or arylboronates (a ruthenium catalyst).[1978] Trialkylboranes have been similarly used to convert thioesters to ketones.[1979] Thioesters give good yields of ketones when treated with lithium dialkylcopper reagents R''_2CuLi (R″ = primary or secondary alkyl or aryl).[1980] Organozinc reagents also convert thioesters to ketones.[1981] Arylboronic acids also react with dialkyl anhydrides, with a rhodium catalyst[1982] or a palladium catalyst,[1983] to give the ketone. Aryl iodides react with acetic anhydride, with a palladium catalyst, to give the aryl methyl ketone.[1984] Diaryl- or dialkylzinc reagents react with anhydrides and a palladium catalyst[1985] or a nickel catalyst[1986] to give the ketone. Note that in the presence of a SmI_2 catalyst and 2 equivalents of allyl bromide, lactones were converted to the diallyl diol.[1987] *N*-(3-Iodopropyl)succinimide derivatives react with SmI_2 and an iron catalyst to give bicyclic pyrrolizidinone derivatives

via intramolecular addition of the organometallic intermediate to one carbonyl.[1988] The reaction of alkylzinc halides and thioesters leads to ketones in the presence of 1.5% Pd/C,[1989] in what has been called *Fukuyama coupling*.[1990]

Carboxylic esters can be converted to their homologs (RCOOEt → RCH_2-COOEt) by treatment with Br_2CHLi followed by BuLi at −90°C. The ynolate RC≡COLi is an intermediate.[1991] If the ynolate is treated with 1,3-cyclohexadiene, followed by $NaBH_4$, the product is the alcohol RCH_2CH_2OH.[1992]

Note that acyl benzotriazoles react with β-keto esters to give diketones via acyl substitution.[1993] Acyl cyanides, RC(=O)CN, react with allylic bromides and indium metal to give the corresponding ketone.[1994] Coupling an acid chloride and a silyl amide, $R_3SiC(=O)NR'_2$, leads to an α-keto amide.[1995] Acyl benzotriazoles have been coupled with SmI_2 to give the 1,2-diketone.[1996] α-Cyanoketone (acyl nitriles) were coupled with YbI_2 in a similar manner.[1997]α-Keto phosphonate esters undergo radical acyl substitution to give cyclic ketones under photochemical conditions.[1998]

Silyl esters are converted to the enolate anion upon treatment with *n*-butyllithium, and subsequent addition of an aldehyde followed by saponification leads to the β-hydroxy acid.[1999]

Vinyl organometallic reagents can be added to acyl derivatives. Reaction of an alkyne with Cp_2ZrEt_2 generates the vinyl zirconium reagent, which react with ethyl chloroformate to give an α,β-unsaturated ester.[2000]

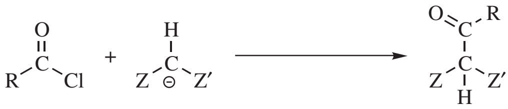
Acyl halides can be coupled with pyrophoric lead to give symmetrical α-diketones in a Wurtz-type reaction.[2001] The reaction has been performed with R = Me and Ph. Samarium iodide SmI_2[2002] gives the same reaction. Benzoyl chloride was coupled to give benzil by subjecting it to ultrasound in the presence of Li wire:

$$2\,PhCOCl + Li \longrightarrow PhCOCOPh.$$ [2003]

Unsymmetrical α-diketones, RCOCR′, have been prepared by treatment of an acyl halide RCOCl with an acyltin reagent ($R'COSnBu_3$), with a palladium complex catalyst.[2004]

16-84 Acylation at a Carbon Bearing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, and so on



This reaction is similar to **10-67**, but there are fewer examples.[2005] Either Z or Z′ may be any of the groups listed in **10-67**.[2006] Anhydrides react similarly but are used less often. The product contains three Z groups, since RCO is a Z group. One or two of these can be cleaved (**12-40**, **12-43**). In this way, a compound ZCH_2Z' can be converted to ZCH_2Z^2 or an acyl halide (RCOCl) to a methyl ketone ($RCOCH_3$). *O*-Acylation is sometimes a side reaction.[2007] When thallium(I) salts of ZCH_2Z' are used, it is possible to achieve regioselective acylation at either the C or the O position. For example, treatment of the thallium(I) salt of $MeCOCH_2COMe$ with acetyl chloride at −78°C gave >90% *O*-acylation, while acetyl fluoride at room temperature gave >95% *C*-acylation.[2008] The use of an alkyl chloroformate gives triesters.[2009]

The application of this reaction to simple ketones[2010] (in parallel with **10-68**) requires a strong base, such as $NaNH_2$ or Ph_3CNa, and is often complicated by

O-acylation, which in many cases becomes the principal pathway because acylation at the oxygen is usually much faster. It is possible to increase the proportion of *C*-acylated product by employing an excess (2–3 equivalents) of enolate anion (and adding the substrate to this, rather than vice versa), by the use of a relatively nonpolar solvent and a metal ion (e.g., Mg^{2+}), which is tightly associated with the enolate oxygen atom, by the use of an acyl halide rather than an anhydride,[2011] and by working at low temperatures.[2012] In cases where the use of an excess of enolate anion results in *C*-acylation, it is because *O*-acylation takes place first, and the *O*-acylated product (an enol ester) is then *C*-acylated. Simple ketones can be acylated by treatment of their silyl enol ethers with an acyl chloride in the presence of $ZnCl_2$ or $SbCl_3$.[2013] Ketones can be acylated by anhydrides to give β-diketones, with BF_3 as catalyst.[2014] Simple esters RCH_2COOEt can be acylated at the a carbon (at −78°C) if a strong base such as lithium *N*-isopropylcyclohexylamide is used to remove the proton.[2015]

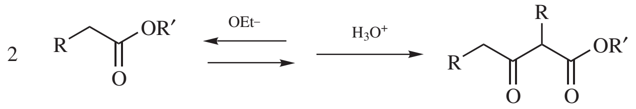
16-85 Acylation of Carboxylic Esters by Carboxylic Esters: The Claisen and Dieckmann Condensations

Alkoxycarbonylalkyl-de-alkoxy-substitution



When carboxylic esters containing an α hydrogen are treated with a strong base, such as sodium ethoxide, a condensation occurs to give a β-keto ester via an ester enolate anion.[2016] This reaction is called the *Claisen condensation*. When it is carried out with a mixture of two different esters, each of which possesses an α hydrogen (this reaction is called a mixed Claisen or a crossed Claisen condensation), a mixture of all four products is generally obtained and the reaction is seldom useful synthetically.[2017] However, if only one of the esters has an

[2011]See House, H.O. *Modern Synthetic Reactions*, 2nd ed., W.A. Benjamin, NY, ***1972***, pp. 762–765; House, H.O.; Auerbach, R.A.; Gall, M.; Peet, N.P. *J. Org. Chem.* ***1973***, *38*, 514.

Chem.* ***1987***, *118*, 415.

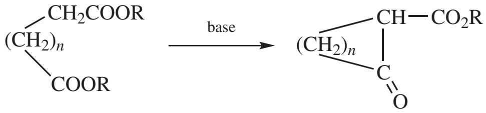
[2016]For a study of ester and amide enolate stabilization, see Rablen, P.R.; Bentrup, KL.H. *J. Am. Chem. Soc.* ***2003***, *125*, 2142.

[2017]For a method of allowing certain crossed-Claisen reactions to proceed with good yields, see Tanabe, Y. *Bull. Chem. Soc. Jpn.* ***1989***, *62*, 1917.

α hydrogen, the mixed reaction is frequently satisfactory. Among esters lacking a hydrogens (hence acting as the substrate ester) that are commonly used in this way are esters of aromatic acids, and ethyl carbonate and ethyl oxalate. When the ester enolate reacts with ethyl carbonate, the product is a malonic ester, and reaction with ethyl formate introduces a formyl group. Claisen condensation of phenyl esters with $ZrCl_4$ and diisopropylethylamine (Hünigs base) give the corresponding keto ester.[2018]

As with ketone enolate anions (see **16-34**), the use of amide bases under kinetic control conditions (strong base with a weak conjugate acid, aprotic solvents, low temperatures), allows the mixed Claisen condensation to proceed. Self-condensation of the lithium enolate with the parent ester is a problem when LDA is used as a base,[2019] but this is minimized with LICA (lithium isopropylcyclohexyl amide).[2020] Note that solvent-free Claisen condensation reactions have been reported.[2021]

When the two ester groups involved in the condensation are in the same molecule, the product is a cyclic β-keto ester and the reaction is called the *Dieckmann condensation*.[2022]



The Dieckmann condensation is most successful for the formation of five-, six-, and seven-membered rings. Yields for rings of 9–12 members are very low or nonexistent; larger rings can be closed with high-dilution techniques. Reactions in which large rings are to be closed are generally assisted by high dilution, since one end of the molecule has a better chance of finding the other end than of finding another molecule. A solvent-free Dieckmann condensation has been reported on solid potassium *tert*-butoxide.[2023] Dieckmann condensation of unsymmetrical substrates can be made regioselective (unidirectional) by the use of solid-phase supports.[2024]

The mechanism of the Claisen and Dieckmann reactions is the ordinary tetrahedral mechanism,[2025] with one molecule of ester being converted to a nucleophile by

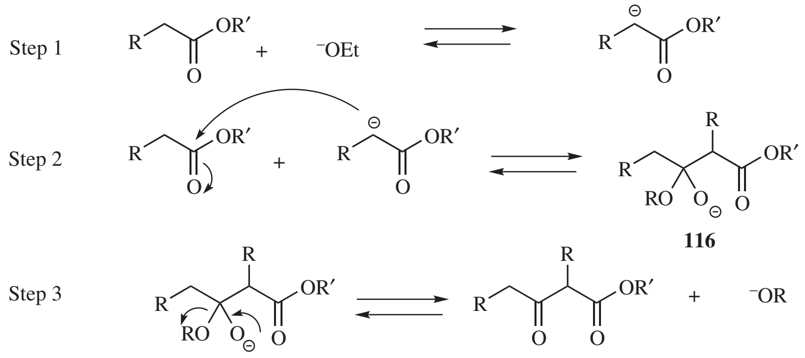
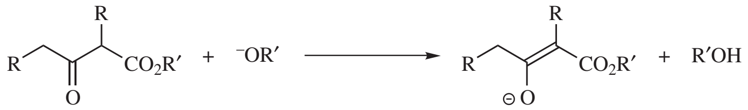
[2025]There is evidence that, at least in some cases, an SET mechanism is involved: Ashby, E.C.; Park, W. *Tetrahedron Lett.* ***1983***, 1667. The transition structures have also been examined by Nishimura, T.; Sunagawa, M.; Okajima, T.; Fukazawa, Y. *Tetrahedron Lett.* ***1997***, *38*, 7063.

the base and the other serving as the substrate.



This reaction illustrates the striking difference in behavior between carboxylic esters on the one hand and aldehydes and ketones on the other. When a carbanion, such as an enolate anion, is added to the carbonyl group of an aldehyde or ketone (**16-38**), the H or R is not lost, since these groups are much poorer leaving groups than OR. Instead the intermediate similar to **116** adds a proton at the oxygen to give a hydroxy compound.

In contrast to **10-67** ordinary esters react quite well, that is, two Z groups are not needed. A lower degree of acidity is satisfactory because it is not necessary to convert the attacking ester entirely to its ion. Step 1 is an equilibrium that lies well to the left. Nevertheless, the small amount of enolate anion formed is sufficient to attack the readily approachable ester substrate. All the steps are equilibria. The reaction proceeds because the product is converted to its conjugate base by the base present (i.e., a β-keto ester is a stronger acid than an alcohol):



The use of a stronger base, such as $NaNH_2$, NaH, or KH,[2026] often increases the yield. For some esters stronger bases *must* be used, since sodium ethoxide is ineffective. Among these are esters of the type $R_2CHCOOEt$, the products of which ($R_2CHCOCR_2COOEt$) lack an acidic hydrogen, so that they cannot be converted to enolate anions by sodium ethoxide.[2027] The Dieckmann condensation has also been done using $TiCl_3/NBu_3$ with a TMSOTf catalyst.[2028] A Dieckmann-like condensation was reported where an α,ω-dicarboxylic acid was hated to 450°C on graphite, with microwave irradiation, to give the cyclic ketone.[2029]

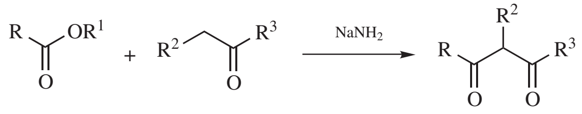
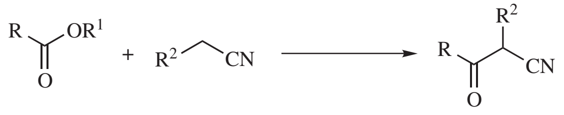
16-86 Acylation of Ketones and Nitriles by Carboxylic Esters

α-Acylalkyl-de-alkoxy-substitution



Carboxylic esters can be treated with ketones to give β-diketones. The reaction is so similar that it is sometimes also called the Claisen reaction, though this usage may be confusing. A strong base, such as sodium amide or sodium hydride, is required. Yields can be increased by the catalytic addition of crown ethers.[2030] Esters of formic acid (R = H) give β-keto aldehydes and ethyl carbonate gives β-keto esters. β-Keto esters can also be obtained by treating the lithium enolates of ketones with methyl cyanoformate MeOCOCN[2031] (in this case CN is the leaving group) and by treating ketones with KH and diethyl dicarbonate, $(EtOCO)_2O$.[2032]

In the case of unsymmetrical ketones, the attack usually comes from the less highly substituted side, so that CH_3 is more reactive than RCH_2, and the R_2CH group rarely attacks. This reaction has been used to effect cyclization, especially to prepare five- and six-membered rings. Nitriles are frequently used instead of ketones, the products being β-keto nitriles.



Other nucleophilic carbon reagents, such as acetylide ions, and ions derived from α-methylpyridines have also been used. A particularly useful nucleophile is the methylsulfinyl carbanion, $CH_3SOCH_2–$,[2033] the conjugate base of DMSO, since the β-keto sulfoxide produced can easily be reduced to a methyl ketone (p. 624). The methylsulfonyl carbanion ($CH_3SO_2CH_2^-$), the conjugate base of dimethyl sulfone, behaves similarly,[2034] and the product can be similarly reduced. Certain carboxylic esters, acyl halides, and DMF will acylate 1,3-dithianes[2035] (see **10-71**) to give, after oxidative hydrolysis with NBS or NCS, α-keto aldehydes or

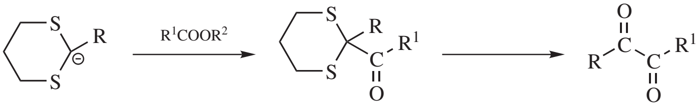
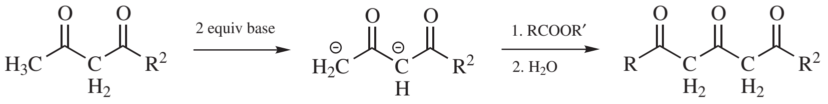
α-diketones,[254] for example,



As in **10-67**, a ketone attacks with its second most acidic position if 2 equivalents of base are used. Thus, β-diketones have been converted to 1,3,5-triketones.[2036]



Side reactions are condensation of the ketone with itself (**16-34**), of the ester with itself, and of the ketone with the ester, but with the ester supplying the a position (**16-36**). The mechanism is the same as in **16-85**.[2037]

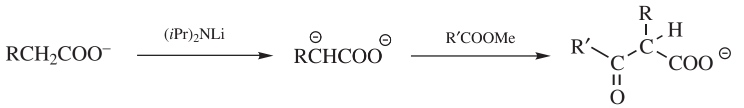
16-87 Acylation of Carboxylic Acid Salts

α-Carboxyalkyl-de-alkoxy-substitution



We have previously seen (**10-70**) that dianions of carboxylic acids can be alkylated in the α position. These ions can also be acylated on treatment with a carboxylic ester[2038] to give salts of β-keto acids. As in **10-70**, the carboxylic acid can be of the form RCH_2COOH or $RR^2CHCOOH$. Since β-keto acids are so easily converted to ketones (**12-40**), this is also a method for the preparation of ketones $R'COCH_2R$ and $R'COCHRR^2$, where R′ can be primary, secondary, or tertiary alkyl, or aryl. If the ester is ethyl formate, an α-formyl carboxylate salt (R′ = H) is formed, which on acidification spontaneously decarboxylates into an aldehyde.[2039] This method accomplishes the conversion $RCH_2COOH \rightarrow RCH_2CHO$, and is an alternative to the reduction methods discussed in **19-39**. When the carboxylic acid is of the form RR″CHCOOH, better yields are obtained by acylating with acyl halides rather than esters.[2040]

16-88 Preparation of Acyl Cyanides

Cyano-de-halogenation

$$\text{RCOX} + \text{CuCN} \longrightarrow \text{RCOCN}$$

Acyl cyanides[2041] can be prepared by treatment of acyl halides with copper cyanide. The mechanism could be free-radical or nucleophilic substitution. The reaction has also been accomplished with thallium(I) cyanide,[2042] with Me_3SiCN and an $SnCl_4$ catalyst,[2043] and with Bu_3SnCN,[2044] but these reagents are successful only when R = aryl or tertiary alkyl. KCN has also been used, along with ultrasound,[2045] as has NaCN with phase-transfer catalysts.[2046]

OS **III**, 119.

16-89 Preparation of Diazo Ketones

Diazomethyl-de-halogenation

$$\text{RCOX} + \text{CH}_2\text{N}_2 \longrightarrow \text{RCOCHN}_2$$

The reaction between acyl halides and diazomethane is of wide scope and is the best way to prepare diazo ketones.[2047] Diazomethane must be present in excess or the HX produced will react with the diazo ketone (**10-52**). This reaction is the first step of the *Arndt–Eistert synthesis* (**18-8**). Diazo ketones can also be prepared directly from a carboxylic acid and diazomethane or diazoethane in the presence of DCC.[2048]

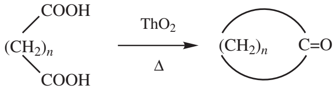
Carboxylic acids can be converted to symmetrical ketones by pyrolysis in the presence of thorium oxide. In a mixed reaction, formic acid and another acid heated over thorium oxide give aldehydes. Mixed alkyl aryl ketones have been prepared by heating mixtures of ferrous salts.[2050] When the R group is large, the methyl ester rather than the acid can be decarbmethoxylated over thorium oxide to give the symmetrical ketone.

The reaction has been performed on dicarboxylic acids, whereupon cyclic ketones are obtained:



This process, called *Ruzicka cyclization*, is good for the preparation of rings of six and seven members and, with lower yields, of C_8 and C_{10}–C_{30} cyclic ketones.[2051]

Not much work has been done on the mechanism of this reaction. However, a free-radical mechanism has been suggested on the basis of a thorough study of all the side products.[2052]

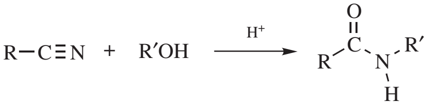
REACTIONS IN WHICH CARBON ADDS TO THE HETEROATOM

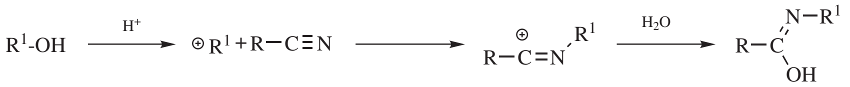
A. Oxygen Adding to the Carbon

16-91 The Ritter Reaction

***N*-Hydro,*N*-alkyl-*C*-oxo-biaddition**



Alcohols can be added to nitriles in an entirely different manner from that of reaction **16-9**. In this reaction, the alcohol is converted by a strong acid to a carbocation, which is attacked by the nucleophilic nitrogen atom to give **117**. Subsequent addition of water to the electrophilic carbon atom leads to the enol form of the amide (see **118**), which tautomerizes (p. 98) to the *N*-alkyl amide.



117 **118**

[2050]Granito, C.; Schultz, H.P. *J. Org. Chem.* ***1963***, *28*, 879.

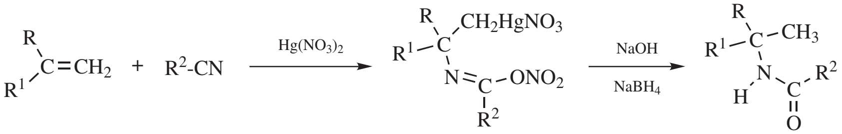
[2051]See, for example, Ruzicka, L.; Stoll, M.; Schinz, H. *Helv. Chim. Acta* ***1926***, *9*, 249; ***1928***, *11*, 1174; Ruzicka, L.; Brugger, W.; Seidel, C.F.; Schinz, H. *Helv. Chim. Acta* ***1928***, *11*, 496.

[2052]Hites, R.A.; Biemann, K. *J. Am. Chem. Soc.* ***1972***, *94*, 5772. See also, Bouchoule, C.; Blanchard, M.; Thomassin, R. *Bull. Soc. Chim. Fr.* ***1973***, 1773.

Only alcohols that give rise to fairly stable carbocations react (secondary, tertiary, benzylic, etc.); non-benzylic primary alcohols do not give the reaction. The carbocation need not be generated from an alcohol, but may come from protonation of an alkene or from other sources. In any case, the reaction is called the *Ritter reaction*.[2053] Lewis acids, such as $Mg(HSO_4)_2$, have been used to promote the reaction.[2054] Highly sterically hindered nitriles have been converted to *N*-methyl amides by heating with methanol and sulfuric acid.[2055] HCN also gives the reaction, the product being a formamide. Trimethylsilyl cyanide has also been used.[2056]

Since the amides (especially the formamides) are easily cleaved under hydrolysis conditions to amines, the Ritter reaction provides a method for achieving the conversions $R'OH \rightarrow R'NH_2$ (see **10-32**) and alkene $\rightarrow R'NH_2$ (see **15-8**) in those cases where R′ can form a relatively stable carbocation. The reaction is especially useful for the preparation of tertiary alkyl amines because there are few alternate ways of preparing these compounds. The reaction can be extended to primary alcohols by treatment with triflic anhydride[2057] or $Ph_2CCl^+ \ SbCl_6^-$ or a similar salt[2058] in the presence of the nitrile.

Alkenes of the form RCH=CHR′ and RR′C=CH_2 add to nitriles in the presence of mercuric nitrate to give, after treatment with $NaBH_4$, the same amides that would be obtained by the Ritter reaction.[2059] This method has the advantage of avoiding strong acids.



Benzylic compounds, such as ethylbenzene, react with alkyl nitriles, ceric ammonium nitrate, and a catalytic amount of *N*-hydroxysuccinimide to give the Ritter product, the amide.[2060]

The Ritter reaction can be applied to cyanamides RNHCN to give ureas RNHCONHR′.[2061]

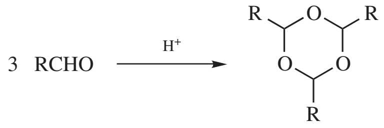
16-92 The Addition of Aldehydes to Aldehydes



When catalyzed by acids, low-molecular-weight aldehydes add to each other to give cyclic acetals, the most common product being the trimer.[2062] The cyclic trimer of formaldehyde is called *trioxane*,[2063] and that of acetaldehyde is known as *paraldehyde*. Under certain conditions, it is possible to get tetramers[2064] or dimers. Aldehydes can also polymerize to linear polymers, but here a small amount of water is required to form hemiacetal groups at the ends of the chains. The linear polymer formed from formaldehyde is called *paraformaldehyde*. Since trimers and polymers of aldehydes are acetals, they are stable to bases, but can be hydrolyzed by acids. Because formaldehyde and acetaldehyde have low boiling points, it is often convenient to use them in the form of their trimers or polymers.

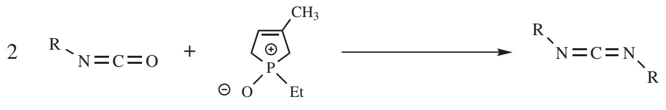
Aryl aldehydes condense with aliphatic aldehydes in the presence of benzoylformate decarboxylase and thiamin diphosphate to give an α-hydroxy ketone with god enantioselectivity.[2065]

A slightly related reaction involves nitriles, which can be trimerized with various acids, bases, or other catalysts to give triazines (see OS **III**, 71).[2066] Here HCl is most often used. Most nitriles with an α hydrogen do not give the reaction.

B. Nitrogen Adding to the Carbon

16-93 The Addition of Isocyanates to Isocyanates (Formation of Carbodiimides)

Alkylimino-de-oxo-bisubstitution



119

The treatment of isocyanates with 3-methyl-1-ethyl-3-phospholene-1-oxide (**119**) is a useful method for the synthesis of carbodiimides[2067] in good

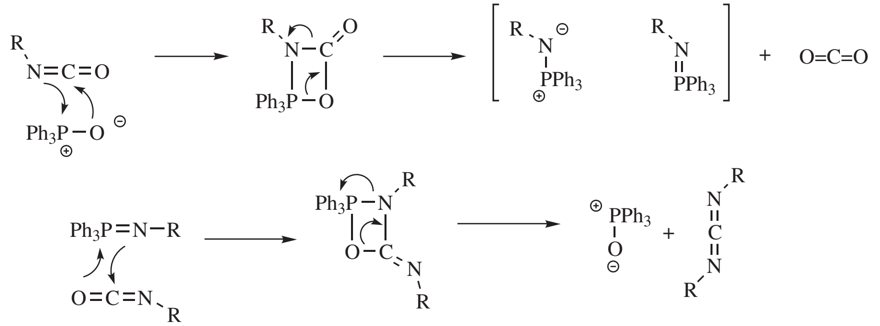
yields.[2068] The mechanism does not simply involve the addition of one molecule of isocyanate to another, since the kinetics are first order in isocyanate and first order in catalyst. The following mechanism has been proposed (the catalyst is here represented as R_3P^+—O^-:[2069]



According to this mechanism, one molecule of isocyanate undergoes addition to C=O, and the other addition to C=N. Evidence is that ^{18}O labeling experiments have shown that each molecule of CO_2 produced contains one oxygen atom derived from the isocyanate and one from **119**,[2070] precisely what is predicted by this mechanism. Certain other catalysts are also effective.[2071] High-load, soluble oligomeric carbodiimides have been prepared.[2072]

OS **V**, 501.

16-94 The Conversion of Carboxylic Acid Salts to Nitriles

Nitrilo-de-oxido,oxo-tersubstitution

$$RCOO^- + BrCN \xrightarrow{250\text{–}300°C} RCN + CO_2$$

Salts of aliphatic or aromatic carboxylic acids can be converted to the corresponding nitriles by heating with BrCN or ClCN. Despite appearances, this is not a substitution reaction. When $R^{14}COO^-$ was used, the label appeared in the nitrile, not in the CO_2,[2073] and optical activity in R was retained.[2074] The acyl isocyanate RCON=C=O could be isolated from the reaction mixture; hence the

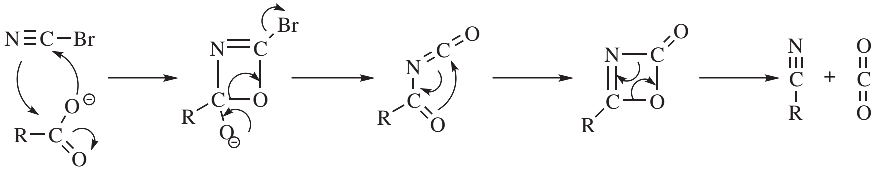
following mechanism was proposed:[2073]

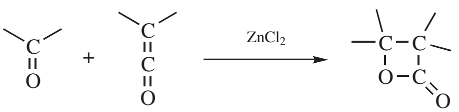


C. Carbon Adding to the Carbon.

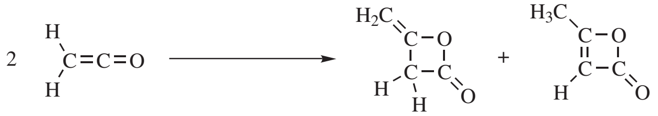
The reactions in this group are cycloadditions.

16-95 The Formation of β-Lactones and Oxetanes

(2+2)*OC*,*CC*-*cyclo*-[oxoethylene]-1/2/addition



Aldehydes, ketones, and quinones react with ketenes to give β-lactones,[2075] diphenylketene being used most often.[2076] The reaction is catalyzed by Lewis acids, and without them most ketenes do not give adducts because the adducts decompose at the high temperatures necessary when no catalyst is used. When ketene was added to chloral (Cl_3CCHO) in the presence of the chiral catalyst (+)-quinidine, one enantiomer of the β-lactone was produced with excellent enantioselectivity.[2077] The use of a chiral aluminum catalyst also led to β-lactones with good syn selectivity and good enantioselectivity.[2078] Other di- and trihalo aldehydes and ketones also give the reaction enantioselectively, with somewhat lower enantioselectivity.[2079] Ketene adds to another molecule of itself:



This dimerization is so rapid that ketene does not form β-lactones with aldehydes or ketones, except at low temperatures. Other ketenes dimerize more slowly. In

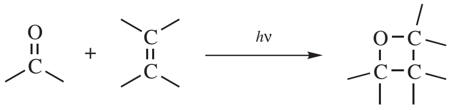
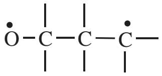
these cases, the major dimerization product is not the β-lactone, but a cyclobutanedione (see **15-63**). However, the proportion of ketene that dimerizes to β-lactone can be increased by the addition of catalysts, such as triethylamine or triethyl phosphite.[2080] Ketene acetals $R_2C{=}C(OR')_2$ add to aldehydes and ketones in the presence of $ZnCl_2$ to give the corresponding oxetanes.[2081]



Ordinary aldehydes and ketones can add to alkenes, under the influence of *UV* light, to give oxetanes. Quinones also react to give spirocyclic oxetanes.[2082] This reaction, called the *Paterno–Büchi reaction*,[2083] is similar to the photochemical dimerization of alkenes discussed at **15-63**. In general, the mechanism consists of the addition of an excited state of the carbonyl compound to the ground state of the alkene. Both singlet (S_1)[2084] and n,π^* triplet[2085] states have been shown to add to alkenes to give oxetanes. A diradical intermediate[2086]



has been detected by spectroscopic methods.[2087] Yields in the Paterno–Büchi reaction are variable, ranging from very low to fairly high (90%). The reaction can be

highly diastereoselective,[2088] and allylic alcohols were shown to react with aldehydes to give an oxetane with syn selectivity.[2089] There are several side reactions. When the reaction proceeds through a triplet state, it can in general be successful only when the alkene possesses a triplet energy comparable to, or higher than, the carbonyl compound; otherwise energy transfer from the excited carbonyl group to the ground-state alkene can take place (triplet-triplet photosensitization, see p. 340).[2090] In most cases, quinones react normally with alkenes, giving oxetane products, but other α,β-unsaturated ketones usually give preferential cyclobutane formation (**15-63**). Aldehydes and ketones also add photochemically to allenes to give the corresponding alkylideneoxetanes and dioxaspiro compounds:[2091] Aldehydes add to silyl enol ethers.[2092] An intramolecular reaction of ketones was reported to give a bicyclic oxetane via photolysis on the solid state.[2093]

RCH=C=O, except when these are generated *in situ* by decomposition of a diazo ketone (the Wolff rearrangement, **18-8**) in the presence of the imine. It has been done with ketene, but the more usual course with this reagent is an addition to the enamine tautomer of the substrate. Thioketenes[2095] ($R_2C=C=S$) give β-thiolactams.[2096] Imines also form β-lactams when treated with (*1*) zinc (or another metal[2097]) and an α-bromo ester (Reformatsky conditions, **16-28**),[2098] or (*2*) the chromium carbene complexes $(CO)_5Cr=C(Me)OMe$.[2099] The latter method has been used to prepare optically active β-lactams.[2100] Ketenes have also been added to certain hydrazones (e.g., $PhCH=NNMe_2$) to give *N*-amino β-lactams.[2101] A polymer-bound pyridinium salt facilitates β-lactam formation from carboxylic acids and imines.[2102]

N-Tosyl imines react with ketenes, Proton Sponge (p. 365) and a chiral amine to give the *N*-tosyl β-lactam with good enantioselectivity.[2103] A chiral ferrocenyl catalyst also gives good enantioselectivity,[2104] and chiral ammonium salts have been used as catalysts.[2105] A catalytic amount of benzoyl quinine gives β-lactams with good enantioselectivity.[2106] An intramolecular version of this ketene-imine reaction is known.[2107]

Like the similar cycloaddition of ketenes to alkenes (**15-63**), most of these reactions probably take place by the diionic mechanism *c* (p. 1224).[2108] β-Lactams have also been prepared in the opposite manner: by the addition of enamines to isocyanates:[2109]

The reactive compound chlorosulfonyl isocyanate ($ClSO_2NCO$)[2110] forms β-lactams even with unactivated alkenes,[2111] as well as with imines,[2112] allenes,[2113] conjugated dienes,[2114] and cyclopropenes.[2115] With microwave irradiation, alkyl isocyanates also react.[2116]

α-Diazo ketones react with imines and microwave irradiation to give β-lactams.[2117] Allylic phosphonate esters react with imines, in the presence of a palladium catalyst, to give β-lactams.[2118] Alkynyl reagents, such as $BuC{\equiv}CO{-}Li^{+}$, react with imines to form β-lactams.[2119] Imines and benzylic halides react to give β-lactams in the presence of CO and a palladium catalyst.[2120] Conjugated amides react with NBS and 20% sodium acetate to give an α-bromo β-lactam.[2121] A different approach to β-lactams heated aziridines with CO and a cobalt catalyst.[2122] Aziridines also react with CO and a dendrimer catalyst to go a β-lactam.[2123]

OS **V**, 673; **VIII**, 3, 216.

ADDITION TO ISOCYANIDES[2124]

Addition to $R{-}^{+}N{\equiv}C^{-}$ is not a matter of a species with an electron pair adding to one atom and a species without a pair adding to the other, as is addition to the other types of double and triple bonds in this chapter and Chapter 15. In these additions, the electrophile and the nucleophile *both add to the carbon*. No species

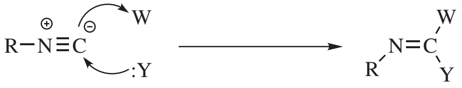
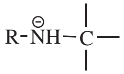
add to the



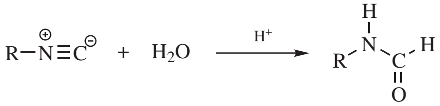
120

nitrogen, which, however, loses its positive charge by obtaining as an unshared pair one of the triple-bond pairs of electrons to give **120**. In most of the reactions considered below, **120** undergoes a further reaction, so the product is of the form.

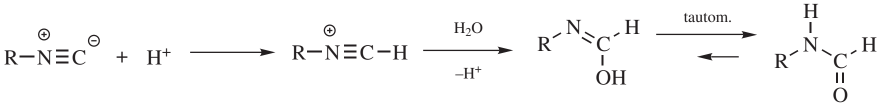


16-97 The Addition of Water to Isocyanides

1/*N*,2/*C*-Dihydro-2/*C*-oxo-biaddition



Formamides can be prepared by the acid-catalyzed addition of water to isocyanides. The mechanism is probably[2125]



The reaction has also been carried out under alkaline conditions, with hydroxide in aqueous dioxane.[2126] The mechanism here involves nucleophilic attack by hydroxide at the carbon atom. An intramolecular addition of an alkyne (in an ortho alkynyl phenyl isonitrile) to the carbon of an isonitrile occurred with heating in methanol to give quinoline derivatives.[2127]

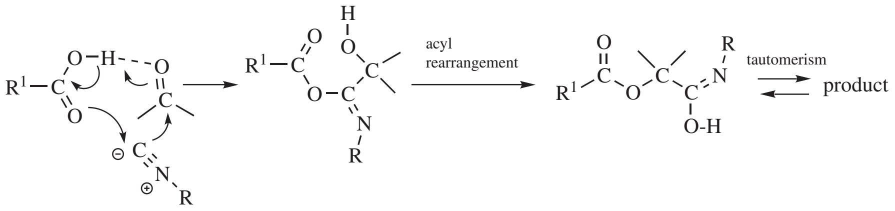
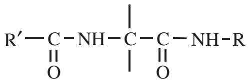
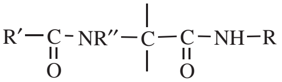
When an isocyanide is treated with a carboxylic acid and an aldehyde or ketone, an α-acyloxy amide is prepared. This is called the *Passerini reaction*. A $SiCl_4$-mediated reaction in the presence of a chiral bis-phosphoramide gives an α-hydroxy amide with good enantioselectivity.[2129] The following mechanism has been postulated for the basic reaction:[2130]



If ammonia or an amine is also added to the mixture (in which case the reaction is known as the *Ugi reaction*, or the *Ugi four-component condensation*, abbreviated 4 CC), the product is the corresponding bis(amide)



(from NH_3) or



(from a primary amine R^2NH_2).

Repetitive Ugi reactions are known.[2131] This product probably arises from a reaction between the carboxylic acid, the isocyanide, and the *imine* formed from the aldehyde or ketone and ammonia or the primary amine. The use of an *N*-protected amino acid[2132] or peptide as the carboxylic acid component and/or the use of an isocyanide containing a C-protected carboxyl group allows the reaction to be used for peptide synthesis.[2133]

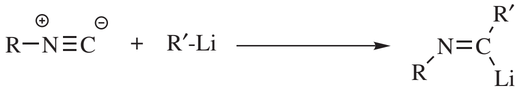
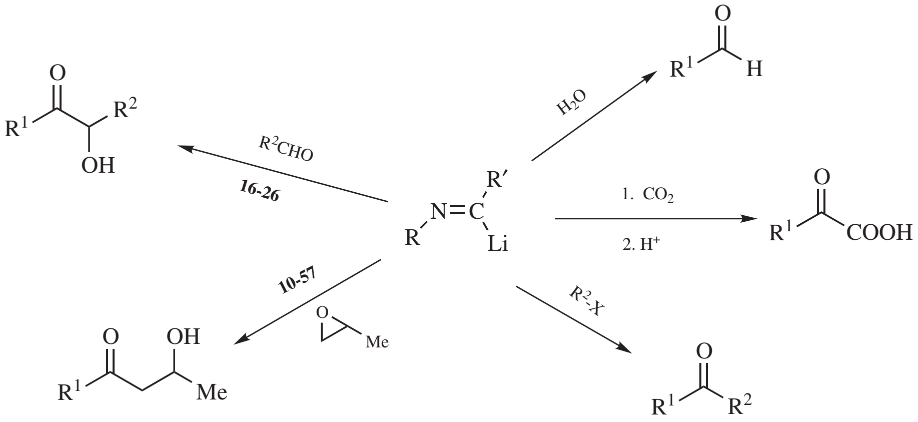
16-99 The Formation of Metalated Aldimines

1/1/Lithio-alkyl-addition



Isocyanides that do not contain an α hydrogen react with alkyllithium compounds,[2134] as well as with Grignard reagents, to give lithium (or magnesium) aldimines.[2135] These metalated aldimines are versatile nucleophiles and react with various substrates as follows:



The reaction therefore constitutes a method for converting an organometallic compound R′M to an aldehyde R′CHO (see also, **12-33**), an α-keto acid,[2136] a ketone R′COR (see also, **12-33**), an α-hydroxy ketone, or a β-hydroxy ketone. In each case, the C=N bond is hydrolyzed to a C=O bond (**16-2**).

[2134]For a review of other metallation reactions of isocyanides, see Ito, Y.; Murakami, M. *Synlett* ***1990***, 245.

See also, Walborsky, H.M.; Ronman, P. *J. Org. Chem.* ***1978***, *43*, 731. For the formation of zinc aldimines, see Murakami, H.; Ito, H.; Ito, Y. *J. Org. Chem.* ***1988***, *53*, 4158.

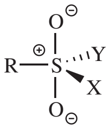
[2136]For a review of the synthesis and properties of α-keto acids, see Cooper, A.J.L.; Ginos, J.Z.; Meister, A. *Chem. Rev.* ***1983***, *83*, 321.

In a related reaction, isocyanides can be converted to aromatic aldimines by treatment with an iron complex followed by irradiation in benzene solution: $RNC + C_6H_6 \rightarrow PhCH{=}NR$.[2137]

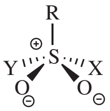
OS **VI**, 751.

NUCLEOPHILIC SUBSTITUTION AT A SULFONYL SULFUR ATOM[2138]

Nucleophilic substitution at RSO_2X is similar to attack at RCOX. Many of the reactions are essentially the same, though sulfonyl halides are less reactive than halides of carboxylic acids.[2139] The mechanisms[2140] are not identical, because a "tetrahedral" intermediate in this case (**121**) would have five groups on the central atom. This is possible since sulfur can accommodate up to 12 electrons in its valence shell, but it seems more likely that these mechanisms more closely resemble the S_N2 mechanism, with a trigonal-bipyramidal transition state (**122**). There are two major experimental results leading to this conclusion.



121



122

1. The stereospecificity of this reaction is more difficult to determine than that of nucleophilic substitution at a saturated carbon, where chiral compounds are relatively easy to prepare, but it may be recalled (p. 142) that optical activity is possible in a compound of the form RSO_2X if one oxygen is ^{16}O and the other ^{18}O. When a sulfonate ester possessing this type of chirality was converted to a sulfone with a Grignard reagent (**16-105**), inversion of configuration was found.[2141] This is not incompatible with an intermediate such as **121** but it is also in good accord with an S_N2-like mechanism with backside attack.

2. More direct evidence against **121** (though still not conclusive) was found in an experiment involving acidic and basic hydrolysis of aryl arenesulfonates, where it has been shown by the use of ^{18}O that an intermediate like **121** is not reversibly formed, since ester recovered when the reaction was stopped before completion contained no ^{18}O when the hydrolysis was carried out in the presence of labeled water.[2142]

Other evidence favoring the S_N2-like mechanism comes from kinetics and substituent effects.[2143] However, evidence for the mechanism involving **121** is that the rates did not change much with changes in the leaving group[2144] and the ρ values were large, indicating that a negative charge builds up in the transition state.[2145]

In certain cases in which the substrate carries an α hydrogen, there is strong evidence[2146] that at least some of the reaction takes place by an elimination-addition mechanism (E1cB, similar to the one shown on p. 1406), going through a *sulfene* intermediate,[2147] for example, the reaction between methanesulfonyl chloride and aniline.

$$CH_3{-}SO_2Cl \xrightarrow{\text{base}} \underset{\text{A sulfene}}{CH_2{=}SO_2} \xrightarrow{PhNH_2} CH_3{-}SO_2{-}NHPh$$

In the special case of nucleophilic substitution at a sulfonic ester RSO_2OR', where R′ is alkyl, R′—O cleavage is much more likely than S—O cleavage because the OSO_2R group is such a good leaving group (p. 497).[2148] Many of these reactions have been considered previously (e.g., **10-4**, **10-10**), because they are nucleophilic substitutions at an alkyl carbon atom and not at a sulfur atom. However, when R′ is aryl, then the S—O bond is much more likely to cleave because of the very low tendency aryl substrates have for nucleophilic substitution.[2149]

The order of nucleophilicity toward a sulfonyl sulfur has been reported as $OH^- > RNH_2 > N_3^- > F^- > AcO^- > Cl^- > H_2O > I^-$.[2150] This order is similar to that at a carbonyl carbon (p. $$$). Both of these substrates can be regarded as relatively hard acids, compared to a saturated carbon which is considerably softer and which has a different order of nucleophilicity (p. 494).

16-100 Attack by OH: Hydrolysis of Sulfonic Acid Derivatives

***S*-Hydroxy-de-chlorination**, etc.

$$RSO_2X \xrightarrow[H_2O + H^+]{H_2O \quad \text{or}} RSO_2OH \qquad (X = Cl, OR', NR'_2)$$

Sulfonyl chlorides as well as esters and amides of sulfonic acids can be hydrolyzed to the corresponding acids. Sulfonyl chlorides can by hydrolyzed with water or with an alcohol in the absence of acid or base. Basic catalysis is also used, though of course the salt is the product obtained. Esters are readily hydrolyzed, many with water or dilute alkali. This is the same reaction as **10-4**, and usually involves R′—O cleavage, except when R′ is aryl. However, in some cases retention of configuration has been shown at alkyl R′, indicating S—O cleavage in these cases.[2151] Sulfonamides are generally *not* hydrolyzed by alkaline treatment, not even with hot concentrated alkali. Acids, however, do hydrolyze sulfonamides, but less readily than they do sulfonyl halides or sulfonic esters. Of course, ammonia or the amine appears as the salt. However, sulfonamides can be hydrolyzed with base if the solvent is HMPA.[2152]

Magnesium in methanol has been used to convert sulfonate esters to the parent alcohol.[2153] Likewise, $CeCl_3 \cdot 7\,H_2O$—NaI in acetonitrile converted aryl tosylates to the parent phenol derivative.[2154]

[2148]A number of sulfonates in which R contains a branching, for example, $Ph_2C(CF_3)SO_2OR'$, can be used to ensure that there will be no S—O cleavage: Netscher, T.; Prinzbach, H. *Synthesis* ***1987***, 683.

16-101 Attack by OR. Formation of Sulfonic Esters

***S*-Alkoxy-de-chlorination**, and so on

$$RSO_2Cl \quad + \quad R'OH \xrightarrow{\text{base}} RSO_2OR'$$

$$RSO_2NR_2'' \quad + \quad R'OH \xrightarrow{\text{base}} RSO_2OR' \quad + \quad NHR_2''$$

Sulfonic esters are most frequently prepared by treatment of the corresponding sulfonyl halides with alcohols in the presence of a base. This procedure is the most common method for the conversion of alcohols to tosylates, brosylates, and similar sulfonic esters. Both R and R′ may be alkyl or aryl. The base is often pyridine, which functions as a nucleophilic catalyst,[2155] as in the similar alcoholysis of carboxylic acyl halides (**16-61**). Propylenediamines have also been used to facilitate tosylation of an alcohol.[2156] Silver oxide has been used, in conjunction with KI.[2157] Primary alcohols react the most rapidly, and it is often possible to sulfonate selectively a primary OH group in a molecule that also contains secondary or tertiary OH groups. The reaction with sulfonamides has been much less frequently used and is limited to *N*,*N*-disubstituted sulfonamides; that is, R— may not be hydrogen. However, within these limits it is a useful reaction. The nucleophile in this case is actually RO^-. However, R′ may be hydrogen (as well as alkyl) if the nucleophile is a phenol, so that the product is RSO_2OAr. Acidic catalysts are used in this case.[2158] Sulfonic acids have been converted directly to sulfonates by treatment with triethyl or trimethyl orthoformate, $HC(OR)_3$, without catalyst or solvent;[2159] and with a trialkyl phosphite, $P(OR)_3$.[2160]

Mono-tosylation of a 1,2-diol was achieved using tosyl chloride and triethylamine, with a tin oxide catalyst.[2161]

16-102 Attack by Nitrogen: Formation of Sulfonamides

S-Amino-de-chlorination

$$RSO_2Cl \quad + \quad NH_3 \longrightarrow RSO_2NH_2$$

The treatment of sulfonyl chlorides with ammonia or amines is the usual way of preparing sulfonamides. Primary amines give *N*-alkyl sulfonamides, and secondary amines give *N*,*N*-dialkyl sulfonamides. The reaction is the basis of the *Hinsberg test* for distinguishing between primary, secondary, and tertiary amines. *N*-Alkyl sulfonamides, having an acidic hydrogen, are soluble in alkali, while *N*,*N*-dialkyl sulfonamides are not. Since tertiary amines are usually recovered unchanged, primary, secondary, and tertiary amines can be told apart. However, the test is limited for at least two reasons.[2162] (*1*) Many *N*-alkyl sulfonamides in which the alkyl group has six or more carbons are insoluble in alkali, despite their acidic hydrogen,[2163] so that a primary amine may appear to be a secondary amine. (*2*) If the reaction conditions are not carefully controlled, tertiary amines may not be recovered unchanged.[2160]

A primary or a secondary amine can be protected by reaction with phenacylsulfonyl chloride, ($PhCOCH_2SO_2Cl$), to give a sulfonamide, $RNHSO_2CH_2COPh$ or $R_2NSO_2CH_2COPh$.[2164] The protecting group can be removed when desired with zinc and acetic acid. Sulfonyl chlorides react with azide ion to give sulfonyl azides (RSO_2N_3).[2165] Chlorothioformates, ROC(=S)Cl, react with triethylamine to give the *N*,*N*-diethylthioamide.[2166]

A quite different synthesis of sulfonamides treated allyltributyltin with PhI=NTs, in the presence of copper (II) triflate.[2167] another alternative method treats silyl enol ethers with sulfur dioxide, and subsequent and reaction with a secondary amine gave the β-sulfonamido ester.[2168]

OS **IV**, 34, 943; **V**, 39, 179, 1055; **VI**, 78, 652; **VII**, 501; **VIII**, 104. See also, OS **VI**, 788.

16-103 Attack by Halogen: Formation of Sulfonyl Halides

S-Halo-de-hydroxylation

$$RSO_2OH \quad + \quad PCl_5 \longrightarrow RSO_2Cl$$

[2162]For directions for performing and interpreting the Hinsberg test, see Gambill, C.R.; Roberts, T.D.; Shechter, H. *J. Chem. Educ.* ***1972***, *49*, 287.

[2168]Bouchez, L.C.; Dubbaka, S.R.; Urks, M.; Vogel, P. *J. Org. Chem.* ***2004***, *69*, 6413.

This reaction, parallel with **16-79**, is the standard method for the preparation of sulfonyl halides. Also used are PCl_3 and $SOCl_2$, and sulfonic acid salts can also serve as substrates. Cyanuric acid (2,4,6-trichloro[1,3,5]triazene) also serves as a chlorinating agent.[2169] Sulfonyl bromides and iodides have been prepared from sulfonyl hydrazides ($ArSO_2NHNH_2$, themselves prepared by **16-102**) by treatment with bromine or iodine.[2170] Sulfonyl fluorides are generally prepared from the chlorides, by halogen exchange.[2171]

OS **I**, 84; **IV**, 571, 693, 846, 937; **V**, 196. See also, OS **VII**, 495.

16-104 Attack by Hydrogen: Reduction of Sulfonyl Chlorides

***S*-Hydro-de-chlorination** or ***S*-Dechlorination**

$$2\ RSO_2Cl \quad + \quad Zn \longrightarrow (RSO_2)_2Zn \xrightarrow{H+} 2\ RSO_2H$$

Sulfinic acids can be prepared by reduction of sulfonyl chlorides. Though mostly done on aromatic sulfonyl chlorides, the reaction has also been applied to alkyl compounds. Besides zinc, sodium sulfite, hydrazine, sodium sulfide, and other reducing agents have been used. For reduction of sulfonyl chlorides to thiols, see **19-78**.

OS **I**, 7, 492; **IV**, 674.

16-105 Attack by Carbon: Preparation of Sulfones

***S*-Aryl-de-chlorination**

$$ArSO_2Cl \quad + \quad Ar'MgX \longrightarrow ArSO_2Ar'$$

Grignard reagents convert aromatic sulfonyl chlorides or aromatic sulfonates to sulfones. Organolithium reagents react with sulfonyl fluorides at −78°C to give the corresponding sulfone.[2172] Aromatic sulfonates have also been converted to sulfones with organolithium compounds,[2173] with aryltin compounds,[2174] and with alkyl halides and Zn metal.[2175] Vinylic and allylic sulfones have been prepared by treatment of sulfonyl chlorides with a vinylic or allylic stannane and a palladium complex catalyst.[2176] Alkynyl sulfones can be prepared by treatment of sulfonyl chlorides with trimethylsilylalkynes, with an $AlCl_3$ catalyst.[2177] Note that

trifluoromethylsulfones were converted to methyl sulfones by reaction with methylmagneisum bromide.[2178]

Arylboronic acids (p. 815) react with sulfonyl chlorides in the presence of $PdCl_2$ to give the corresponding sulfone.[2179] arylboronic acids also react with sulfinate anions (RSO_2Na) in the presence of $Cu(OAc)_2$ to give the sulfone.[2180]

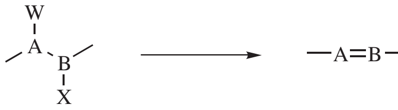
CHAPTER 17

Eliminations

When two groups are lost from adjacent atoms so that a new double[1]



(or triple) bond is formed the reaction is called β-*elimination*; one atom is the α, the other the β atom. In an α elimination, both groups are lost from the same atom to give a carbene (or a nitrene):

In a γ elimination, a three-membered ring is formed:

Some of these processes were discussed in Chapter 10. Another type of elimination involves the expulsion of a fragment from within a chain or ring (X–Y–Z → X–Z + Y). Such reactions are called *extrusion reactions*. This chapter discusses β-elimination and (beginning on p. 1553) extrusion reactions; however, β-elimination in which both X and W are hydrogens are oxidation reactions and are treated in Chapter 19.

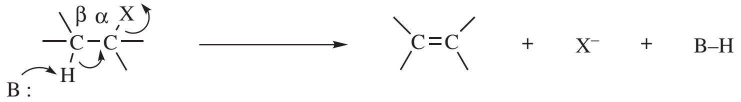
MECHANISMS AND ORIENTATION

β-Elimination reactions may be divided into two types; one type taking place largely in solution, the other (pyrolytic eliminations) mostly in the gas phase. In the reactions in solution, one group leaves with its electrons and the other without, the latter most often being hydrogen. In these cases, we refer to the former as the leaving group or nucleofuge. For pyrolytic eliminations, there are two principal mechanisms, one pericyclic and the other a free-radical pathway. A few photochemical eliminations are also known (the most important is Norrish type II cleavage of ketones, p. 344), but these are not generally of synthetic importance[2] and will not be discussed further. In most β-eliminations the new bonds are C=C or C≡C; our discussion of mechanisms is largely confined to these cases.[3] Mechanisms in solution (E2, E1)[4] and E1cB are discussed first.

The E2 Mechanism

In the E2 mechanism (elimination, bimolecular), the two groups depart simultaneously, with the proton being pulled off by a base:



The mechanism thus takes place in one step and kinetically is second order: first order in substrate and first order in base. An *ab initio* study has produced a model for the E2 transition state geometry.[5] The IUPAC designation is $A_{xH}D_HD_N$, or more generally (to include cases where the electrofuge is not hydrogen), $A_nD_ED_N$. It is analogous to the S_N2 mechanism (p. 426) and often competes with it. With respect

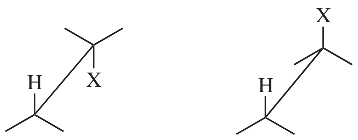
to the substrate, the difference between the two pathways is whether the species with the unshared pair attacks the carbon (and thus acts as a nucleophile) or the hydrogen (and thus acts as a base). As in the case of the S_N2 mechanism, the leaving group may be positive or neutral and the base may be negatively charged or neutral.

Among the evidence for the existence of the E2 mechanism are (*1*) the reaction displays the proper second-order kinetics; (*2*) when the hydrogen is replaced by deuterium in second-order eliminations, there is an isotope effect of from 3 to 8, consistent with breaking of this bond in the rate-determining step.[6] However, neither of these results alone could prove an E2 mechanism, since both are compatible with other mechanisms also (e.g., see E1cB p. 1488). The most compelling evidence for the E2 mechanism is found in stereochemical studies.[7] As will be illustrated in the examples below, the E2 mechanism is stereospecific: The five atoms involved (including the base) in the transition state must be in one plane. There are two ways for this to happen. The H and X may be



A **B**

trans to one another (**A**) with a dihedral angle of 180°, or they may be cis (**B**) with a dihedral angle of 0°.[8] Conformation **A** is called *anti-periplanar*, and this type of elimination, in which H and X depart in opposite directions, is called *anti-elimination*. Conformation **B** is *syn-periplanar*, and this type of elimination, with H and X leaving in the same direction, is called *syn-elimination*. Many examples of both kinds have been discovered. In the absence of special effects (discussed below) anti-elimination is usually greatly favored over syn-elimination, probably because **A** is a staggered conformation (p. 199) and the molecule requires less energy to reach this transition state than it does to reach the eclipsed transition state **B**. A few of the many known examples of predominant or exclusive anti-elimination follow.

[6]See, for example, Saunders, Jr., W.H.; Edison, D.H. *J. Am. Chem. Soc.* ***1960***, *82*, 138; Shiner, Jr., V.J.; Smith, M.L. *J. Am. Chem. Soc.* ***1958***, *80*, 4095; ***1961***, *83*, 593. 1. Elimination of HBr from *meso*-1,2-dibromo-1,2-diphenylethane gave *cis*-2-bromostilbene, while the (+) or (−) isomer gave the trans alkene. This stereospecific result, which

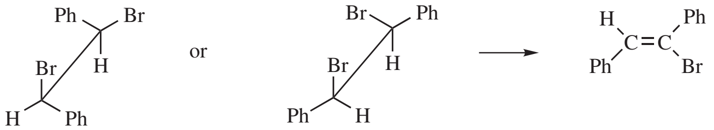
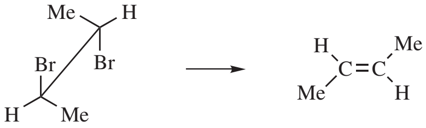
meso cis

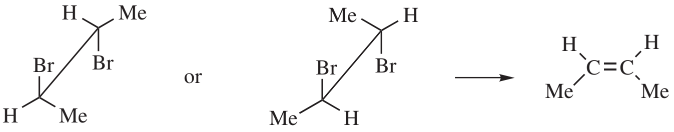


dl pair trans

was obtained in 1904,[9] demonstrates that in this case elimination is anti. Many similar examples have been discovered since. Obviously, this type of experiment need not be restricted to compounds that have a meso form. Anti-elimination requires that an erythro *dl* pair (or either isomer) give the cis alkene, and the threo *dl* pair (or either isomer) give the trans isomer, and this has been found many times. Anti-elimination has also been demonstrated in cases where the electrofuge is not hydrogen. In the reaction of 2,3-dibromobutane with iodide ion, the two bromines are removed (**17-22**). In this case, the meso compound gave the trans alkene and the *dl* pair the cis:[10]



meso trans

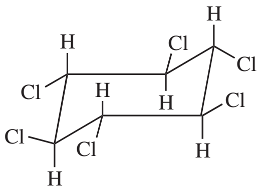


dl pair cis

2. In open-chain compounds, the molecule can usually adopt that conformation in which H and X are anti-periplanar. However, in cyclic systems this is not always the case. There are nine stereoisomers of 1,2,3,4,5,6-hexachlorocyclohexane: seven meso forms and a *dl* pair (see p. 165). Four of the meso compounds and the *dl* pair (all that were then known) were subjected to

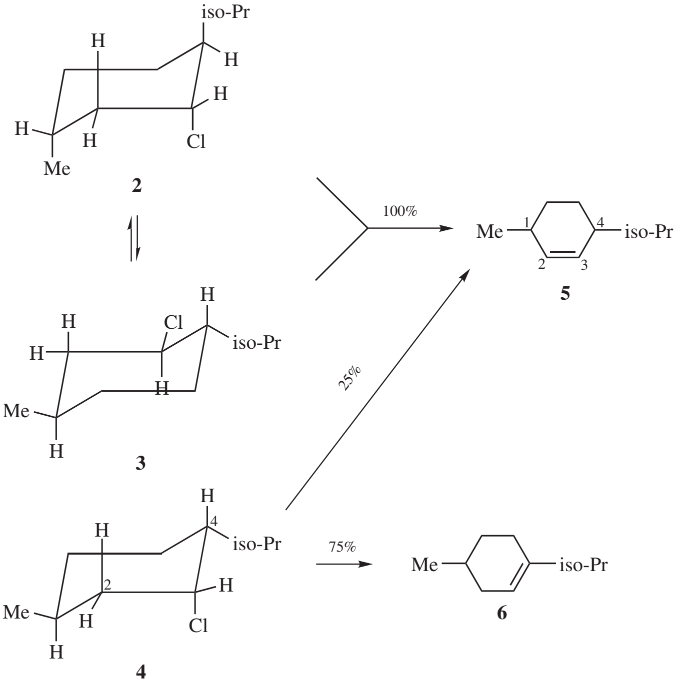
[9]Pfeiffer, P. *Z. Phys. Chem.* ***1904***, *48*, 40.
[10]Winstein, S.; Pressman, D.; Young, W.G. *J. Am. Chem. Soc.* ***1939***, *61*, 1645.

elimination of HCl. Only one of these (**1**) has no Cl trans to an H. Of the other isomers, the fastest elimination rate was about three times as fast as the slowest, but the rate for **1** was 7000 times slower than that of the slowest of the other isomers.[11] This result demonstrates that with these compounds anti elimination is greatly favored over syn elimination, although the latter must be taking place on **1**, very slowly, to be sure.



1

3. The preceding result shows that elimination of HCl in a six-membered ring proceeds best when the H and X are trans to each other. However, there is an additional restriction. Adjacent trans groups on a six-membered ring can be diaxial or diequatorial (p. 204) and the molecule is generally free to adopt either conformation, although one may have a higher energy than the other. Anti-periplanarity of the leaving groups requires that they be diaxial, even if this is the conformation of higher energy. The results with menthyl and neomenthyl chlorides are easily



[11]Cristol, S.J.; Hause, N.L.; Meek, J.S. *J. Am. Chem. Soc.* ***1951***, *73*, 674.

interpretable on this basis. Menthyl chloride has two chair conformations, **2** and **3**. Compound **3**, in which the three substituents are all equatorial, is the more stable. The more stable chair conformation of neomenthyl chloride is **4**, in which the chlorine is axial; there are axial hydrogens on both C-2 and C-4. The results are: neomenthyl chloride gives rapid E2 elimination and the alkene produced is predominantly **6** (**6**/**5** ratio is 3:1) in accord with Zaitsev's rule (p. 767). Since an axial hydrogen is available on both sides, this factor does not control the direction of elimination and Zaitsev's rule is free to operate. However, for menthyl chloride, elimination is much slower and the product is entirely the anti-Zaitsev, **5**. It is slow because the unfavorable conformation **2** has to be achieved before elimination can take place, and the product is **5** because only on this side is there an axial hydrogen.[12]

4. That anti-elimination also occurs in the formation of triple bonds is shown by elimination from *cis*- and *trans*-HOOC–CH=C(Cl)COOH. In this case, the product in both cases is HOOCC≡CCOOH, but the trans isomer reacts ~50 times faster than the cis compound.[13]

Some examples of syn-elimination have been found in molecules where H and X could not achieve an anti-periplanar conformation.

1. The deuterated norbornyl bromide (**7**, X = Br) gave 94% of the product containing no deuterium.[14] Similar results were obtained with other leaving groups and with bicyclo[2.2.2] compounds.[15] In these cases the exo X group cannot achieve a dihedral angle of 180° with the endo β hydrogen because of the rigid structure of the molecule. The dihedral angle here is ~120°. These leaving groups prefer syn-elimination with a dihedral angle of ~0° to anti-elimination with an angle of ~120°.

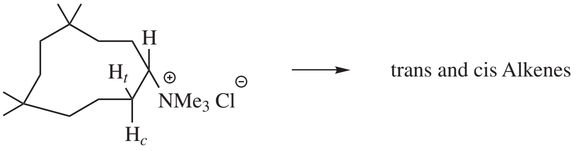
Chem.* ***1970***, *35*, 2750; Brown, H.C.; Liu, K. *J. Am. Chem. Soc.* ***1970***, *92*, 200; Sicher, J.; Pánkova, M.; Závada, J.; Kniežo, L.; Orahovats, A. *Collect. Czech. Chem. Commun.* ***1971***, *36*, 3128; Bartsch, R.A.; Lee, J.G. *J. Org. Chem.* ***1991***, *56*, 212, 2579.

2. Molecule **8** is a particularly graphic example of the need for a planar transition state. In **8**, each Cl has an adjacent hydrogen trans to it, and if planarity of leaving groups were not required, anti-elimination could easily take place. However, the crowding of the rest of the molecule forces the dihedral angle to be ~120°, and elimination of HCl from **8** is much slower than from corresponding nonbridged compounds.[16] (Note that syn elimination from **8** is even less likely than anti-elimination.) Syn-elimination can take place from the trans isomer of **8** (dihedral angle ~0°); this isomer reacted about eight times faster than **8**.[16]

The examples so far given illustrate two points. (*1*) Anti-elimination *requires* a dihedral angle of 180°. When this angle cannot be achieved, anti-elimination is greatly slowed or prevented entirely. (*2*) For the simple systems so far discussed syn-elimination is not found to any significant extent unless anti elimination is greatly diminished by failure to achieve the 180° angle.

As noted in Chapter 4 (p. 223), six-membered rings are the only ones among rings of 4–13 members in which strain-free anti-periplanar conformations can be achieved. It is not surprising, therefore, that syn elimination is least common in six-membered rings. Cooke and Coke subjected cycloalkyltrimethylammonium hydroxides to elimination (**17-7**) and found the following percentages of syn-elimination with ring size: four-membered, 90%; five-membered, 46%; six-membered, 4% seven-membered, 31 to 37%.[17] Note that the NMe_3^+ group has a greater tendency to syn-elimination than do other common leaving groups, such as OTs, Cl, and Br.

Other examples of syn-elimination have been found in medium-ring compounds, where both cis and trans alkenes are possible (p. 184). As an illustration, we can look at experiments performed by, Svoboda, and Sicher.[18] These workers subjected 1,1,4,4-tetramethyl-7-cyclodecyltrimethylammonium chloride (**9**) to



9

elimination and obtained mostly *trans*-, but also some *cis*-tetramethylcyclodecenes as products. (Note that *trans*-cyclodecenes, although stable, are less stable than the cis isomers). In order to determine the stereochemistry of the reaction, they repeated the elimination, this time using deuterated substrates. They found that

[16]Cristol, S.J.; Hause, N.L. *J. Am. Chem. Soc.* ***1952***, *74*, 2193.

[17]Cooke, Jr., M.P.; Coke, J.L. *J. Am. Chem. Soc.* ***1968***, *90*, 5556. See also, Coke, J.L.; Smith, G.D.; Britton, Jr., G.H. *J. Am. Chem. Soc.* ***1975***, *97*, 4323.

[18]Závada, J.; Svoboda, M.; Sicher, J. *Tetrahedron Lett.* ***1966***, 1627; *Collect. Czech. Chem. Commun.* ***1968***, *33*, 4027.

when **9** was deuterated in the trans position ($H_t = D$), there was a substantial isotope effect in the formation of *both* cis and trans alkenes, but when **9** was deuterated in the cis position ($H_c = D$), there was *no* isotope effect in the formation of either alkene. Since an isotope effect is expected for an E2 mechanism,[19] these results indicated that *only* the trans hydrogen (H_t) was lost, whether the product was the cis or the trans isomer.[20] This in turn means that *the cis isomer must have been formed by anti-elimination and the trans isomer by syn-elimination.* (Anti-elimination could take place from approximately the conformation shown, but for syn elimination the molecule must twist into a conformation in which the C–H_t and C–NMe_3^+ bonds are syn-periplanar.) This remarkable result, called the *syn–anti dichotomy*, has also been demonstrated by other types of evidence.[21] The fact that syn-elimination in this case predominates over anti (as indicated by the formation of trans isomer in greater amounts than cis) has been explained by conformational factors.[22] The syn–anti dichotomy has also been found in other medium-ring systems (8–12 membered),[23] although the effect is greatest for 10-membered rings. With leaving groups,[24] the extent of this behavior decreases in the order $^+NMe_3 > OTs > Br > Cl$, which parallels steric requirements. When the leaving group is uncharged, syn-elimination is favored by strong bases and by weakly ionizing solvents.[25]

Syn-elimination and the syn—anti dichotomy have also been found in open-chain systems, although to a lesser extent than in medium-ring compounds. For example, in the conversion of 3-hexyl-4-*d*-trimethylammonium ion to 3-hexene with potassium *sec*-butoxide, ~67% of the reaction followed the syn–anti dichotomy.[26] In general syn-elimination in open-chain systems is only important in cases where certain types of steric effect are present. One such type is compounds in which substituents are found on both the β′ and the γ carbons (the unprimed letter refers to the branch in which the elimination takes place). The factors that cause these results are not

[19]Other possible mechanisms, such as E1cB (p. 1488) or α′,β elimination (p. 1524), were ruled out in all these cases by other evidence.

[20]This conclusion has been challenged by Coke, J.L. *Sel. Org. Transform* ***1972***, *2*, 269.

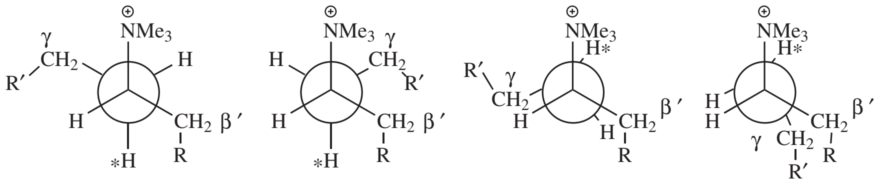
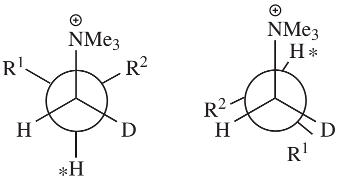
[26]Bailey, D.S.; Saunders Jr., W.H. *J. Am. Chem. Soc.* ***1970***, *92*, 6904. For other examples of syn-elimination and the syn-anti dichotomy in open-chain systems, see Pánková, M.; Vítek, A.; Vasíšková, S.; Řeřicha, R.; Závada, J. *Collect. Czech. Chem. Commun.* ***1972***, *37*, 3456; Schlosser, M.; An, T.D. *Helv. Chim. Acta* ***1979***, *62*, 1194; Sugita, T.; Nakagawa, J.; Nishimoto, K.; Kasai, Y.; Ichikawa, K. *Bull. Chem. Soc. Jpn.* ***1979***, *52*, 871; Pánková, M.; Kocián, O.; Krupička, J.; Závada, J. *Collect. Czech. Chem. Commun.* ***1983***, *48*, 2944.

completely understood, but the following conformational effects have been proposed as a partial explanation.[27] The two anti- and two syn-periplanar conformations are, for a quaternary ammonium salt:



C anti ⟶ trans   D anti ⟶ cis   E syn ⟶ trans   F syn ⟶ cis

In order for an E2 mechanism to take place, a base must approach the proton marked *. In **C**, this proton is shielded on both sides by R and R′. In **D**, the shielding is on only one side. Therefore, when anti-elimination does take place in such systems, it should give more cis product than trans. Also, when the normal anti elimination pathway is hindered sufficiently to allow the syn pathway to compete, the anti → trans route should be diminished more than the anti → cis route. When syn-elimination begins to appear, it seems clear that **E**, which is less eclipsed than **F**, should be the favored pathway and syn-elimination should generally give the trans isomer. In general, deviations from the syn–anti dichotomy are greater on the trans side than on the cis. Thus, trans alkenes are formed partly or mainly by syn-elimination, but cis alkenes are formed entirely by anti-elimination. Predominant syn-elimination has also been found in compounds of the form $R^1R^2CHCHDNMe_3^+$, where R^1 and R^2 are both bulky.[28] In this case, the conformation leading to syn-elimination (**H**) is also less strained than **G**, which gives anti-elimination. The **G** compound has three bulky groups (including NMe_3^+) in the *gauche* position to each other.



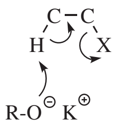
G   H

It was mentioned above that weakly ionizing solvents promote syn-elimination when the leaving group is uncharged. This is probably caused by ion pairing, which

[27]Bailey, D.S.; Saunders, Jr., W.H. *J. Am. Chem. Soc.* ***1970***, *92*, 6904; Chiao, W.; Saunders, Jr., W.H. *J. Am. Chem. Soc.* ***1977***, *99*, 6699.

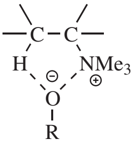
[28]Dohner, B.R.; Saunders Jr., W.H. *J. Am. Chem. Soc.* ***1986***, *108*, 245.

is greatest in nonpolar solvents.[29] Ion pairing can



10

cause syn-elimination with an uncharged leaving group by means of the transition state shown in **10**. This effect was graphically illustrated by elimination from 1,1,4,4-tetramethyl-7-cyclodecyl bromide.[30] The ratio of syn-to-anti-elimination when this compound was treated with *t*-BuOK in the nonpolar benzene was 55.0. But when the crown ether dicyclohexano-18-crown-6 was added (this compound selectively removes K^+ from the *t*-BuO^- K^+ ion pair and thus leaves *t*-BuO^- as a free ion), the syn/anti ratio decreased to 0.12. Large decreases in the syn/anti ratio on addition of the crown ether were also found with the corresponding tosylate and with other nonpolar solvents.[31] However, with positively charged leaving groups the effect is reversed. Here, ion pairing *increases* the amount of anti-elimination.[32] In this case, a relatively free base (e.g., PhO^-) can be attracted to the leaving group, putting it in a favorable position for attack on the syn β hydrogen, while ion pairing would reduce this attraction.



We can conclude that anti-elimination is generally favored in the E2 mechanism, but that steric (inability to form the anti-periplanar transition state), conformational, ion pairing, and other factors cause syn-elimination to intervene (and even predominate) in some cases.

[29]For reviews of ion pairing in this reaction, see Bartsch, R.A.; Závada, J. *Chem. Rev.* ***1980***, *80*, 453; Bartsch, R.A. *Acc. Chem. Res.* ***1975***, *8*, 239.

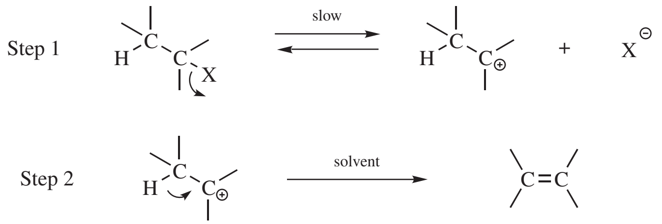
The E1 Mechanism

The E1 mechanism is a two-step process in which the rate-determining step is ionization of the substrate to give a carbocation that rapidly loses a β proton to a base, usually the solvent:

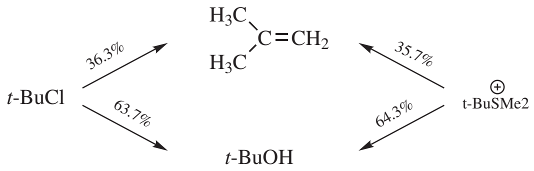


The IUPAC designation is $D_N + D_E$ (or $D_N + D_H$). This mechanism normally operates without an *added* base. Just as the E2 mechanism is analogous to and competes with the S_N2, so is the E1 mechanism related to the S_N1. In fact, the first step of the E1 is exactly the same as that of the S_N1 mechanism. The second step differs in that the solvent pulls a proton from the β carbon of the carbocation rather than attacking it at the positively charged carbon, as in the S_N1 process. In a pure E1 reaction (without ion pairs, etc.), the product should be completely nonstereospecific, since the carbocation is free to adopt its most stable conformation before giving up the proton.

Some of the evidence for the E1 mechanism is as follows:

1. The reaction exhibits first-order kinetics (in substrate) as expected. Of course, the solvent is not expected to appear in the rate equation, even if it were involved in the rate-determining step (p. 316), but this point can be easily checked by adding a small amount of the conjugate base of the solvent. It is generally found that such an addition does not increase the rate of the reaction. If this more powerful base does not enter into the rate-determining step, it is unlikely that the solvent does. An example of an E1 mechanism with a rate-determining second step (proton transfer) has been reported.[33]
2. If the reaction is performed on two molecules that differ only in the leaving group (e.g., *t*-BuCl and *t*-$BuSMe_2^+$), the rates should obviously be different, since they depend on the ionizing ability of the molecule. However, once the carbocation is formed, if the solvent and the temperature are the same, it should suffer the same fate in both cases, since the nature of the leaving group does not affect the second step. This means that *the ratio of elimination to substitution should be the same*. The compounds mentioned in the example were solvolyzed at 65.3°C in 80% aqueous ethanol with the following results:[34]

[33]Baciocchi, E.; Clementi, S.; Sebastiani, G.V.; Ruzziconi, R. *J. Org. Chem.* ***1979***, *44*, 32.
[34]Cooper, K.A.; Hughes, E.D.; Ingold, C.K.; MacNulty, B.J. *J. Chem. Soc.* ***1948***, 2038.



Although the rates were greatly different (as expected with such different leaving groups), the product ratios were the same, within 1%. If this had taken place by a second-order mechanism, the nucleophile would not be expected to have the same ratio of preference for attack at the β hydrogen compared to attack at a *neutral* chloride as for attack at the β hydrogen compared to attack at a *positive* SMe_2 group.

3. Many reactions carried out under first-order conditions on systems where E2 elimination is anti proceed quite readily to give alkenes where a cis hydrogen must be removed, often in preference to the removal of a trans hydrogen. For example, menthyl chloride (**2**, p. 1482), which by the E2 mechanism gave only **5**, under E1 conditions gave 68% **6** and 32% **5**, since the steric nature of the hydrogen is no longer a factor here, and the more stable alkene (Zaitsev's rule, p. 1482) is predominantly formed.

4. If carbocations are intermediates, we should expect rearrangements with suitable substrates. These have often been found in elimination reactions performed under E1 conditions.

E1 reactions can involve ion pairs, just as is true for S_N1 reactions (p. 437).[35] This effect is naturally greatest for nondissociating solvents: It is least in water, greater in ethanol, and greater still in acetic acid. It has been proposed that the ion-pair mechanism (p. 439) extends to elimination reactions too, and that the S_N1, S_N2, E1, and E2 mechanisms possess in common an ion-pair intermediate, at least occasionally.[36]

The E1cB Mechanism[37]

In the E1 mechanism, X leaves first and then H. In the E2 mechanism, the two groups leave at the same time. There is a third possibility: The H leaves first,

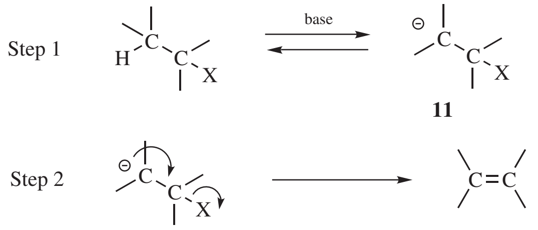
and then the X. This is a two-step process, called the E1cB *mechanism*,[38] or the *carbanion mechanism*, since the intermediate is a carbanion:



The name E1cB comes from the fact that it is the conjugate base of the substrate that is giving up the leaving group (see the S_N1cB mechanism, p. 521). The IUPAC designation is $A_nD_E + D_N$ or $A_{xh}D_H + D_N$ (see p. 420). We can distinguish three limiting cases: (*1*) The carbanion returns to starting material faster than it forms product: step 1 is reversible; step 2 is slow. (*2*) Step 1 is the slow step, and formation of product is faster than return of the carbanion to starting material. In this case, step 1 is essentially irreversible. (*3*) Step 1 is rapid, and the carbanion goes slowly to product. This case occurs only with the most stable carbanions. Here, too, step 1 is essentially irreversible. These cases have been given the designations: (*1*) $(E1cB)_R$, (*2*) $(E1cB)_I$ (or $E1cB_{irr}$), and (*3*) $(E1)_{anion}$. Their characteristics are listed in Table 17.1.[39] Investigations of the reaction order are generally not very useful (except for case 3, which is first order), because cases 1 and 2 are second order and thus difficult or impossible to distinguish from the E2 mechanism by this procedure.[40] We would expect the greatest likelihood of finding the E1cB mechanism in substrates that have (a) a poor nucleofuge and (b) an acidic hydrogen, and most investigations have concerned such substrates. The following is some of the evidence in support of the E1cB mechanism:

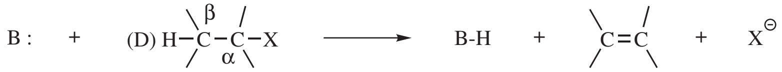
1. The first step of the $(E1cB)_R$ mechanism involves a reversible exchange of protons between the substrate and the base. In that case, if deuterium is present in the base, recovered starting material should contain deuterium. This was found to be the case in the treatment of $Cl_2C{=}CHCl$ with NaOD to give $ClC{\equiv}CCl$. When the reaction was stopped before completion, there *was*

[38]For a discussion, see Ryberg, P.; Matsson, O. *J. Org. Chem.* ***2002***, *67*, 811.

[39]This table, which appears in Cockerill, A.F.; Harrison, R.G. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 9, Elsevier, NY, ***1973***, p. 161, was adapted from a longer one, in Bordwell, F.G. *Acc. Chem. Res.* ***1972***, *5*, 374, see p. 375.

[40]$(E1cB)_I$ cannot be distinguished from E2 by this means, because it has the identical rate law: Rate $= k$[substrate][B^-]. The rate law for $(E1cB)_R$ is different: Rate $= k$[substrate][B^-]/[BH], but this is often not useful because the only difference is that the rate is also dependent (inversely) on the concentration of the conjugate acid of the base, and this is usually the solvent, so that changes in its concentration cannot be measured.

TABLE 17.1. Kinetic Predictions for Base-Induced β-Eliminations[39]



Mechanism	Kinetic[a] Order	β-Hydrogen Exchange Faster Than Elimination	General or Specific Base Catalysis	k_H/k_D	Electron Withdrawal at Cβ[d]	Electron release at Cα[d]	Leaving-Group Isotope Effect or Element Effect
$(E1)_{anion}$	1	Yes	General[c]	1.0	Rate decrease	Rate increase	Substantial
$(E1cB)_R$	2	Yes	Specific	1.0	Small rate increase	Small rate increase	Substantial
$(E1cB)_{ip}$	2	No	General[e]	1.0 → 1.2	Small rate increase	Small rate increase	Substantial
$(E1cB)_I$	2	No	General	2 → 8	Rate increase	Little effect	Small to negligible
E2[b]	2	No	General	2 → 8	Rate increase	Small rate increase	Small

[a]All mechanism exhibit first-order kinetics in substrate.
[b]Only transition states with considerable carbanion character considered in this table.
[c]Specific base catalysis predicted if extent of substrate ionization reduced from almost complete.
[d]Effect on rate assuming no change in mechanism is caused; steric factors upon substitution at Cα and rise to Cβ have not been considered. The rate reductions are geared to substituent effects such as those giving rise to Hammett reaction constants on β- and α-aryl substitution.
[e]Depends on whether an ion pair assists in removal of leaving group.

deuterium in the recovered alkene.[41] A similar result was found for pentahaloethanes.[42] These substrates are relatively acidic. In both cases the electron-withdrawing halogens increase the acidity of the hydrogen, and in the case of trichloroethylene there is the additional factor that a hydrogen on an sp^2 carbon is more acidic than one on an sp^3 carbon (p. 388). Thus, the E1cB mechanism is more likely to be found in eliminations yielding triple bonds than in those giving double bonds. Another likely place for the E1cB mechanism should be in reaction of a substrate like $PhCH_2CH_2Br$, since the carbanion is stabilized by resonance with the phenyl group. Nevertheless, no deuterium exchange was found here.[43] If this type of evidence is a guide, then it may be inferred that the $(E1cB)_R$ mechanism is quite rare, at least for eliminations with common leaving groups such as Br, Cl, or OTs, which yield C=C double bonds.

2. When the reaction

$$p\text{-}NO_2C_6H_4\text{—}CH_2\text{—}\overset{\oplus}{CH_2}\text{—}NR_4 + B^{\ominus} \longrightarrow p\text{-}NO_2C_6H_4\text{—}CH_2{=}CH_2 + BH + NR_3$$

was carried out in water containing acetohydroxamate buffers, a plot of the rate against the buffer concentration was curved and the rate leveled off at high buffer concentrations, indicating a change in rate-determining step.[44] This rules out an E2 mechanism, which has only one step.[45] When D_2O was used instead of H_2O as solvent, there was an initial inverse solvent isotope effect of 7.7 (the highest inverse solvent isotope effect yet reported).

That is, the reaction took place faster in D_2O than in H_2O. This is compatible only with an E1cB mechanism in which the proton-transfer step is not entirely rate determining. The isotope effect arises from a partitioning of the carbanion intermediate **11**. This intermediate either can go to product or it can revert to starting compound, which requires taking a proton from the solvent. In D_2O, the latter process is slower (because the O–D bond of D_2O cleaves less easily than the O–H bond of H_2O), reducing the rate at which **11** returns to starting compound. With the return reaction competing less effectively, the rate of conversion of **11** to product is increased.

3. We have predicted that the E1cB mechanism would most likely be found with substrates containing acidic hydrogens and poor leaving groups. Compounds of the type ZCH_2CH_2OPh, where Z is an electron-withdrawing group (e.g., NO_2, SMe_2^+, $ArSO_2$, CN, COOR), belong to this category, because OPh is a very poor leaving group (p. 438). There is much evidence to show that the mechanism here is indeed E1cB.[46] Isotope effects, measured for $MeSOCD_2CH_2OPh$ and $Me_2S^+CD_2CH_2OPh$ with NaOD in D_2O, are ~0.7. This is compatible with an $(E1cB)_R$ mechanism, but not with an E2 mechanism for which an isotope effect of perhaps 5 might be expected (of course, an E1 mechanism is precluded by the extremely poor nucleofugal ability of OPh). The fact that k_H/k_D is less than the expected value of 1 is attributable to solvent and secondary isotope effects. Among other evidence for an E1cB mechanism in these systems is that changes in the identity of Z had a dramatic effect on the relative rates: a span of 10^{11} between NO_2 and COO^-. Note that elimination from substrates of the type $RCOCH_2CH_2Y$ is the reverse of Michael-type addition to C=C bonds. We have seen (p. $$$) that such addition involves initial attack by a nucleophile Y and subsequent attack by a proton. Thus the initial loss of a proton from substrates of this type (i.e., an E1cB mechanism) is in accord with the principle of microscopic

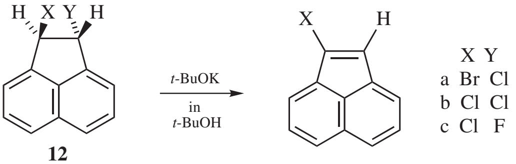
reversibility.[47] It may also be recalled that benzyne formation (p. 859) can occur by such a process. It has been suggested that all base-initiated eliminations wherein the proton is activated by a strong electron-withdrawing group are E1cB reactions,[48] but there is evidence that this is not the case that when there is a good nucleofuge, the mechanism is E2 even when strong electron-withdrawing groups are present.[49] On the other hand, Cl^- has been found to be a leaving group in an E1cB reaction.[50]

Of the three cases of the E1cB mechanism, the one most difficult to distinguish from E2 is $(\text{E1cB})_{\text{I}}$. One way to make this distinction is to study the effect of a change in leaving group. This was done in the case of the three acenaphthylenes **12**, where it was found that (*1*) the three rates were fairly similar, the largest being only about



12

four times that of the smallest, and (*2*) in compound *c* (X = Cl, Y = F), the only product contained Cl and no F, that is, only the poorer nucleofuge F departed while Cl remained.[51] Result (*1*) rules out all the E1cB mechanisms except $(\text{E1cB})_{\text{I}}$, because the others should all have considerable leaving group effects (Table 17.1). An ordinary E2 mechanism should also have a large leaving group effect, but an E2 mechanism with substantial carbanionic character (see the next section) might not. However, no E2 mechanism can explain result (*2*), which can be explained by the fact that an a Cl is more effective than an a F in stabilizing the planar carbanion that remains when the proton is lost. Thus (as in the somewhat similar case of aromatic nucleophilic substitution, see p. 868), when X^- leaves in the second step, the one that leaves is not determined by which is the better nucleofuge, but by which has had its β hydrogen removed.[52] Additional evidence for the existence of the

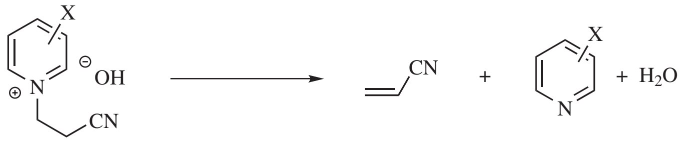
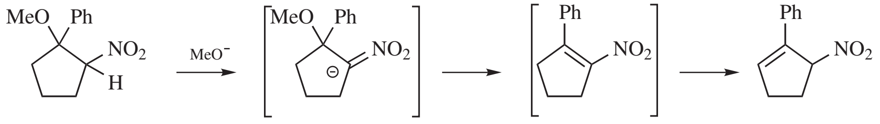
$(E1cB)_I$ mechanism was the observation of a change in the rate-determining step in the elimination reaction of *N*-(2-cyanoethyl)pyridinium



13

ions **13**, treated with base, when X was changed.[53] Once again, the demonstration that two steps are involved precludes the one-step E2 mechanism.

4. An example of an $(E1)_{anion}$ mechanism has been found with the substrate **14**, which when treated with methoxide ion undergoes elimination to **16**, which is unstable under the reaction conditions and rearranges as

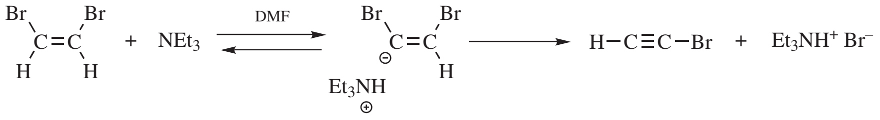


14 15 16

shown.[54] Among the evidence for the proposed mechanism in this case were kinetic and isotope-effect results, as well as the spectral detection of **15**.[55]

5. In many eliminations to form C=O and C≡N bonds the initial step is loss of a positive group (normally a proton) from the oxygen or nitrogen. These may also be regarded as E1cB processes.

There is evidence that some E1cB mechanisms can involve carbanion ion pairs, for example,[56]



This case is designated $(E1cB)_{ip}$; its characteristics are shown in Table 17.1.

The E1-E2-E1cB Spectrum

In the three mechanisms so far considered, the similarities are greater than the differences. In each case, there is a leaving group that comes off with its pair of electrons and another group (usually hydrogen) that comes off without them. The only difference is in the order of the steps. It is now generally accepted that there is a spectrum of mechanisms ranging from one extreme, in which the leaving group departs well before the proton (pure E1), to the other extreme, in which the proton comes off first and then, after some time, the leaving group follows (pure E1cB). The *pure* E2 case would be somewhere in the middle, with both groups leaving simultaneously. However, most E2 reactions are not exactly in the middle, but somewhere to one side or the other. For example, the nucleofuge might depart just before the proton. This case may be described as an E2 reaction with a small amount of E1 character. The concept can be expressed by the question: In the transition state, which bond (C–H or C–X) has undergone more cleavage?[57]

One way to determine just where a given reaction stands on the E1-E2-E1cB spectrum is to study isotope effects, which ought to tell something about the behavior of bonds in the transition state.[58] For example, $CH_3CH_2NMe_3^+$ showed a nitrogen isotope effect (k^{14}/k^{15}) of 1.017, while $PhCH_2CH_2NMe_3^+$ gave a corresponding value of 1.009.[59] It would be expected that the phenyl group would move the reaction toward the E1cB side of the line, which means that for this compound the C–N bond is not as greatly broken in the transition state as it is for the unsubstituted one. The isotope effect bears this out, for it shows that in the phenyl compound, the mass of the nitrogen has less effect on the reaction rate than it does in the unsubstituted compound. Similar results have been obtained with SR_2^+ leaving groups by the use of $^{32}S/^{34}S$ isotope effects[60] and with Cl ($^{35}Cl/^{37}Cl$).[61] The position of reactions along the spectrum has also been studied from the other side of the newly forming double bond by the use of H/D and H/T isotope effects,[62] although interpretation of these results is clouded by the fact that β hydrogen isotope effects are expected to change smoothly from small to large to small again as the degree of transfer of the

Soc.* ***1988***, *110*, 4582; Smith, P.J.; Amin, M. *Can. J. Chem.* ***1989***, *67*, 1457.

β hydrogen from the β carbon to the base increases[63] (recall, p. $$$, that isotope effects are greatest when the proton is half-transferred in the transition state), by the possibility of secondary isotope effects (e.g., the presence of a β deuterium or tritium may cause the leaving group to depart more slowly), and by the possibility of tunneling.[64] Other isotope-effect studies have involved labeled a or β carbon, labeled a hydrogen, or labeled base.[58]

Another way to study the position of a given reaction on the spectrum involves the use of β-aryl substitution. Since a positive Hammet ρ value is an indication of a negatively charged transition state, the ρ value for substituted β-aryl groups should increase as a reaction moves from E1- to E1cB-like along the spectrum. This has been shown to be the case in a number of studies;[65] for example, ρ values of $ArCH_2CH_2X$ increase as the leaving-group ability of X decreases. A typical set of ρ values was X = I, 2.07; Br, 2.14; Cl, 2.61; SMe_2^+, 2.75; F, 3.12.[66] As we have seen, decreasing leaving-group ability correlates with increasing E1cB character.

Still another method measures volumes of activation.[67] These are negative for E2 and positive for E1cB mechanisms. Measurement of the activation volume therefore provides a continuous scale for deciding just where a reaction lies on the spectrum.

The E2C Mechanism[68]

Certain alkyl halides and tosylates undergo E2 eliminations faster when treated with such weak bases as Cl^- in polar aprotic solvents or PhS^- than with the usual E2 strong bases, such as RO^- in ROH.[69] In order to explain these results, Parker

[63]There is controversy as to whether such an effect has been established in this reaction: See Cockerill, A.F. *J. Chem. Soc. B* ***1967***, 964; Blackwell, L.F. *J. Chem. Soc. Perkin Trans. 2* ***1976***, 488.

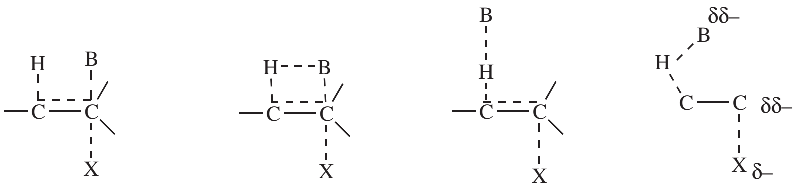
and co-workers proposed[70] that there is a spectrum[71] of E2 transition states in which the base can interact in the transition state with the α carbon, as well as with the β hydrogen. At one end of this spectrum is



E2C 　 **17** 　 E2H 　 **18**

a mechanism (called E2C) in which, in the transition state, the base interacts mainly with the carbon. The E2C mechanism is characterized by strong nucleophiles that are weak bases. At the other extreme is the normal E2 mechanism, here called E2H to distinguish it from E2C, characterized by strong bases. Transition state **17** represents a transition state between these extremes. Additional evidence[72] for the E2C mechanism is derived from Brønsted equation considerations (p. 373), from substrate effects, from isotope effects, and from the effects of solvents on rates.

However, the E2C mechanism has been criticized, and it has been contended that all the experimental results can be explained by the normal E2 mechanism.[73] McLennan has suggested that the transition state is that shown as **18**.[74] An ion-pair mechanism has also been proposed.[75] Although the actual mechanisms involved may be a matter of controversy, there is no doubt that a class of elimination reactions exists that is characterized by second-order attack by weak bases.[76] These reactions also have the following general characteristics:[77] (*1*) they are favored by good leaving groups; (*2*) they are favored by polar aprotic solvents;

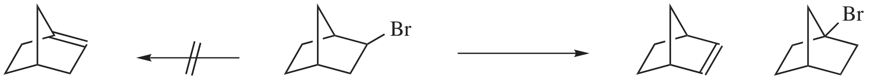
(*3*) the reactivity order is tertiary > secondary > primary, the opposite of the normal E2 order (p. 1503); (*4*) the elimination is always anti- (syn-elimination is not found), but in cyclohexyl systems, a diequatorial anti-elimination is about as favorable as a diaxial anti-elimination (unlike the normal E2 reaction, p. 1481); (*5*) they follow Zaitsev's rule (see below), where this does not conflict with the requirement for anti-elimination.

Regiochemistry of the Double Bond

With some substrates, a β hydrogen is present on only one carbon and (barring rearrangements) there is no doubt as to the identity of the product. For example, $PhCH_2CH_2Br$ can give only $PhCH{=}CH_2$. However, in many other cases two or three alkenyl products are possible. In the simplest such case, a *sec*-butyl compound can give either 1- or 2-butene. There are a number of rules that enable us to predict, in many instances, which product will predominantly form.[78]

1. No matter what the mechanism, a double bond does not go to a bridgehead carbon unless the ring sizes are large enough (Bredt's rule, see p. 229). This means, for example, not only that **19** gives only **20** and not **21** (indeed **21** is not a known compound), but also that **22** does not undergo elimination.



21 **19** **20** **22**

2. No matter what the mechanism, if there is a double bond (C=C or C=O) or an aromatic ring already in the molecule that can be in conjugation with the new double bond, the conjugated product usually predominates, sometimes even when the stereochemistry is unfavorable (for an exception, see p. 1501).
3. In the E1 mechanism the leaving group is gone before the choice is made as to which direction the new double bond takes. Therefore the direction is determined almost entirely by the relative stabilities of the two (or three) possible alkenes. In such cases, *Zaitsev's rule*[79] operates. This rule states that *the double bond goes mainly toward the most highly substituted carbon*. That is, a *sec*-butyl compound gives more 2-butene than 1-butene, and 3-bromo-2,3-dimethylpentane gives more 2,3-dimethyl-2-pentene than either 3,4-dimethyl-2-pentene or 2-ethyl-3-methyl-1-butene. Thus Zaitsev's rule predicts that the alkene predominantly formed will be the one with the largest possible number of alkyl groups on the C=C carbons, and in most cases this is what is found. From heat of combustion data (see p. 29) it is known that

[78]For a review of orientation in cycloalkyl systems, see Hückel, W.; Hanack, M. *Angew. Chem. Int. Ed.* ***1967***, *6*, 534.
[79]Often given the German spelling: Saytzeff.

alkene stability increases with alkyl substitution, although just why this should be is a matter of conjecture. The most common explanation is hyperconjugation. For E1 eliminations, Zaitsev's rule governs the orientation whether the leaving group is neutral or positive, since, as already mentioned, the leaving group is not present when the choice of direction is made. This statement does not hold for E2 eliminations, and it may be mentioned here, for contrast with later results, that E1 elimination of $Me_2CHCHMeSMe_2^+$ gave 91% of the Zaitsev product and 9% of the other.[80] However, there *are* cases in which the leaving group affects the direction of the double bond in E1-eliminations.[81] This may be attributed to ion pairs; that is, the leaving group is not completely gone when the hydrogen departs. Zaitsev's rule breaks down in cases where the non-Zaitsev product is more stable for steric reasons. For example, E1 or E1-like eliminations of 1,2-diphenyl-2-X-propanes $PhMeCXCH_2Ph$ were reported to give ~50% $CH_2{=}CPhCH_2Ph$, despite the fact that the double bond of the Zaitsev product ($PhMeC{=}CHPh$) is conjugated with two benzene rings.[82]

4. For the anti E2 mechanism a trans β proton is necessary; if this is available in only one direction, that is the way the double bond will form. Because of the free rotation in acyclic systems (except where steric hindrance is great), this is a factor only in cyclic systems. Where trans β hydrogens are available on two or three carbons, two types of behavior are found, depending on substrate structure and the nature of the leaving group. Some compounds follow Zaitsev's rule and give predominant formation of the most highly substituted alkene, but others follow *Hofmann's rule: The double bond goes mainly toward the least highly substituted carbon.* although many exceptions are known, the following general statements can be made: In most cases, compounds containing uncharged nucleofuges (those that come off as negative ions) follow Zaitsev's rule, just as they do in E1 elimination, no matter what the structure of the substrate. However, elimination from compounds with charged nucleofuges, for example, NR_3^+, SR_2^+ (those that come off as neutral molecules), follow Hofmann's rule if the substrate is acyclic,[83] but Zaitsev's rule if the leaving group is attached to a six-membered ring.[84]

Much work has been devoted to searching for the reasons for the differences in orientation. Since Zaitsev orientation almost always gives the

[80]de la Mare, P.B.D. *Prog. Stereochem.* ***1954***, *1*, 112.

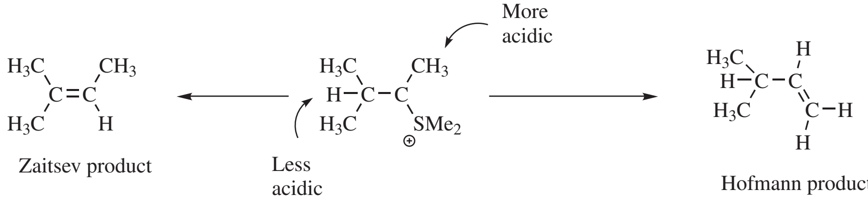
[82]Ho, I.; Smith, J.G. *Tetrahedron* ***1970***, *26*, 4277.

[83]An example of an acyclic quaternary ammonium salt that follows Zaitsev's rule is found, in Feit, I.N.; Saunders, Jr., W.H. *J. Am. Chem. Soc.* ***1970***, *92*, 5615.

[84]For examples where Zaitsev's rule is followed with charged leaving groups in cyclohexyl systems, see Gent, B.B.; McKenna, J. *J. Chem. Soc.* ***1959***, 137; Hughes, E.D.; Wilby, J. *J. Chem. Soc.* ***1960***, 4094; Brownlee, T.H.; Saunders Jr., W.H. *Proc. Chem. Soc.* ***1961***, 314; Booth, H.; Franklin, N.C.; Gidley, G.C. *J. Chem. Soc. C* ***1968***, 1891. For a discussion of the possible reasons for this, see Saunders, Jr., W.H.; Cockerill, A.F. *Mechanisms of Elimination Reactions*, Wiley, NY, ***1973***, pp. 192–193.

thermodynamically more stable isomer, what needs to be explained is why in some cases the less stable Hofmann product predominates. Three explanations have been offered for the change in orientation in acyclic systems with a change from uncharged to charged nucleofuges. The first of these, by Hughes and Ingold,[85] is that Hofmann orientation is caused by the fact that the acidity of the β hydrogen is decreased by the presence of the electron-donating alkyl groups. For example, under E2 conditions $Me_2CHCHMeSMe_2^+$ gives more of the Hofmann product; it is the more acidic hydrogen that is removed by the base.



Of course, the CH_3 hydrogens would still be more acidic than the Me_2CH hydrogen even if a neutral leaving group were present, but the explanation of Hughes and Ingold is that acidity matters with charged and not with neutral leaving groups, because the charged groups exert a strong electron-withdrawing effect, making differences in acidity greater than they are with the less electron-withdrawing neutral groups.[85] The explanation of Bunnett[86] is similar. According to this, the change to a positive leaving group causes the mechanism to shift toward the E1cB end of the spectrum, where there is more C–H bond breaking in the rate-determining step and where, consequently, acidity is more important. In this view, when there is a neutral leaving group, the mechanism is more E1-like, C–X bond breaking is more important, and alkene stability determines the direction of the new double bond. The third explanation, by H.C. Brown, is completely different. In this picture, field effects are unimportant, and the difference in orientation is largely a steric effect caused by the fact that charged groups are usually larger than neutral ones. A CH_3 group is more open to attack than a CH_2R group and a CHR_2 group is still less easily attacked. Of course, these considerations also apply when the leaving group is neutral, but, according to Brown, they are much less important here because the neutral groups are smaller and do not block access to the hydrogens as much. Brown showed that Hofmann elimination increases with the size of the leaving group. Thus the percentage of 1-ene obtained from $CH_3CH_2CH_2CHXCH_3$ was as follows (X listed in order of increasing size): Br, 31%; I, 30%; OTs, 48%; SMe_2^+, 87%; SO_2Me, 89%;

[85]For summaries of this position, see Ingold, C.K. *Proc. Chem. Soc.* ***1962***, 265; Banthorpe, D.V.; Hughes, E.D.; Ingold, C.K. *J. Chem. Soc.* ***1960***, 4054.
[86]Bunnett, J.F. *Surv. Prog. Chem.* ***1969***, *5*, 53.

NMe_3^+, 98%.[87] Hofmann elimination was also shown to increase with increase in bulk of the substrate.[88] With large enough compounds, Hofmann orientation can be obtained even with halides, for example, *tert*-amyl bromide ogave 89% of the Hofmann product. Even those who believe in the acidity explanations concede that these steric factors operate in extreme cases.[89]

There is one series of results incompatible with the steric explanation E2 elimination from the four 2-halopentanes gave the following percentages of 1-pentene: F, 83%; Cl, 37%; Br, 25%; I, 20%.[90] The same order was found for the four-2-halohexanes.[91] Although there is some doubt about the relative steric requirements of Br, Cl, and I, there is no doubt that F is the smallest of the halogens, and if the steric explanation were the only valid one, the fluoroalkanes could not give predominant Hofmann orientation. Another result that argues against the steric explanation is the effect of changing the nature of the base. An experiment in which the effective size of the base was kept constant while its basicity was increased (by using as bases a series of $XC_6H_4O^-$ ions) showed that the percentage of Hofmann elimination increased with increasing base strength, although the size of the base did not change.[92] These results are in accord with the explanation of Bunnett, since an increase in base strength moves an E2 reaction closer to the E1cB end of the spectrum. In further experiments, a large series of bases of different kinds was shown to obey linear free-energy relationships between basicity and percentage of Hofmann elimination,[93] although certain very large bases (e.g., 2,6-di-*tert*-butyl-phenoxide) did not obey the relationships, steric effects becoming important in these cases. How large the base must be before steric effects are observed depends on the pattern of alkyl substitution in the substrate, but not on the nucleofuge.[94] One further result may be noted. In the gas phase, elimination of H and BrH^+ or H and ClH^+ using Me_3N as the base predominantly followed Hofmann's rule,[95] although BrH^+ and ClH^+ are not very large.

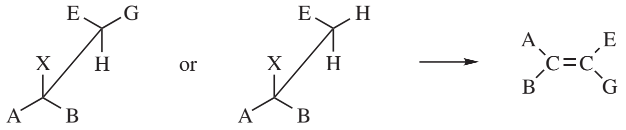
5. Only a few investigations on the orientation of syn E2 eliminations have been carried out, but these show that Hofmann orientation is greatly favored over Zaitsev.[96]
6. In the E1cB mechanism the question of orientation seldom arises because the mechanism is generally found only where there is an electron-withdrawing group in the β position, and that is where the double bond goes.
7. As already mentioned, E2C reactions show a strong preference for Zaitsev orientation.[97] In some cases, this can be put to preparative use. For example, the compound $PhCH_2CHOTsCHMe_2$ gave ~98% $PhCH{=}CHCHMe_2$ under the usual E2 reaction conditions (*t*-BuOK in *t*-BuOH). In this case, the double bond goes to the side with more hydrogens because on that side it will be able to conjugate with the benzene ring. However, with the weak base $Bu_4N^+ Br^-$ in acetone the Zaitsev product $PhCH_2CH{=}CMe_2$ was formed in 90% yield.[98]

Stereochemistry of the Double Bond

When elimination takes place on a compound of the form CH_3–CABX or CHAB–CGGX, the new alkene does not have cis–trans isomerism, but for compounds of the form CHEG–CABX (E and G *not* H) (**23**) and CH_2E–CABX (**24**), cis and trans isomers are possible. When the anti E2 mechanism is in operation, **23** gives the isomer



23 **24**

arising from trans orientation of X and H and, as we have seen before (p. 1478), an erythro compound gives the cis alkene and a threo compound the trans. For **24**, two conformations are possible for the transition state; these lead to different isomers and often both are obtained. However, the one that predominates is often determined by an eclipsing effect.[99] For example, Zaitsev elimination from 2-bromopentane can occur as follows:

[96]Sicher, J.; Svoboda, M.; Pánková, M.; Závada, J. *Collect. Czech. Chem. Commun.* ***1971***, *36*, 3633; Bailey, D.S.; Saunders, Jr., W.H. *J. Am. Chem. Soc.* ***1970***, *92*, 6904.

[97]For example; see Ono, N. *Bull. Chem. Soc. Jpn.* ***1971***, *44*, 1369; Bailey, D.S.; Saunders, Jr., W.H. *J. Org. Chem.* ***1973***, *38*, 3363; Muir, D.M.; Parker, A.J. *J. Org. Chem.* ***1976***, *41*, 3201.

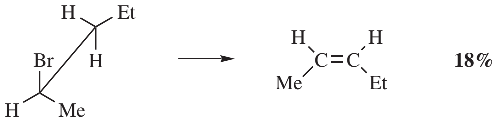
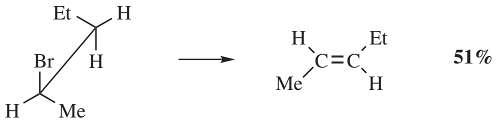
[99]See Cram, D.J.; Greene, F.D.; DePuy, C.H. *J. Am. Chem. Soc.* ***1956***, *78*, 790; Cram, D.G., in Newman, M.S. *Steric Effects in Organic Chemistry*, Wiley, NY, ***1956***, pp. 338–345.



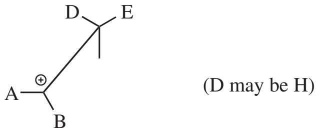
I



J

In conformation **I**, the ethyl group is between Br and Me, while in **J** it is between Br and H. This means that **J** is more stable, and most of the elimination should occur from this conformation. This is indeed what happens, and 51% of the trans isomer is formed (with KOEt) compared to 18% of the cis (the rest is the Hofmann product).[100] These effects become larger with increasing size of A, B, and E.

However, eclipsing effects are not the only factors that affect the cis/trans ratio in anti E2 eliminations. Other factors are the nature of the leaving group, the base, the solvent, and the substrate. Not all these effects are completely understood.[101]



25

For E1 eliminations, if there is a free carbocation (**25**), it is free to rotate, and no matter what the geometry of the original compound, the more stable situation is the one where the larger of the D–E pair is opposite the smaller of the A–B pair and the corresponding alkene should form. If the carbocation is not completely free, then to that extent, E2-type products are formed. Similar considerations apply in E1cB eliminations.[102]

REACTIVITY

In this section, we examine the effects of changes in the substrate, base, leaving group, and medium on (*1*) overall reactivity, (*2*) E1 versus E2 versus E1cB,[103] and (*3*) elimination versus substitution.

Effect of Substrate Structure

1. *Effect on Reactivity.* We refer to the carbon containing the nucleofuge (X) as the a carbon and to the carbon that loses the positive species as the β carbon. Groups attached to the α or β carbons can exert at least four kinds of influence:

   a. They can stabilize or destabilize the incipient double bond (both α and β groups).

   b. They can stabilize or destabilize an incipient negative charge, affecting the acidity of the proton (β groups only).

   c. They can stabilize or destabilize an incipient positive charge (α groups only).

   d. They can exert steric effects (e.g., eclipsing effects) (both α and β groups).

   Effects a and d can apply in all three mechanisms, although steric effects are greatest for the E2 mechanism. Effect b does not apply in the E1 mechanism, and effect c does not apply in the E1cB mechanism. Groups, such as Ar and C=C, increase the rate by any mechanism, except perhaps when formation of the C=C bond is not the rate-determining step, whether they are α or β (effect a). Electron-withdrawing groups increase the acidity when in the β position, but have little effect in the a position unless they also conjugate with the double bond. Thus Br, Cl, CN, Ts, NO_2, CN, and SR in the β position all increase the rate of E2 eliminations.

2. *Effect on* E1 *versus* E2 *versus* E1cB. The α alkyl and α aryl groups stabilize the carbocation character of the transition state, shifting the spectrum toward the E1 end. β alkyl groups also shift the mechanism toward E1, since they *decrease* the acidity of the hydrogen. However, β aryl groups shift the mechanism the other way (toward E1cB) by stabilizing the carbanion. Indeed, as we have seen (p. $$$), all electron-withdrawing groups in the β position shift the mechanism toward E1cB.[104] α alkyl groups also increase the extent of elimination with weak bases (E2C reactions).

3. *Effect on Elimination versus Substitution.* Under second-order conditions, a branching increases elimination, to the point where tertiary substrates undergo few S_N2 reactions, as we saw in Chapter 10. For example, Table 17.2 shows results on some simple alkyl bromides. Similar results were obtained with SMe_2^+ as the leaving group.[105] Two reasons can be presented for this trend. One is statistical: As a branching increases, there are usually more hydrogens for the base to attack. The other is that a branching presents steric hindrance to attack of the base at the carbon. Under first-order conditions, increased a branching also increases the amount of elimination (E1 vs. S_N1), although not

[104]For a review of eliminations with COOH, COOR, $CONH_2$, and CN groups in the β position, see Butskus, P.F.; Denis, G.I. *Russ. Chem. Rev.* ***1966***, *35*, 839.

TABLE 17.2. The Effect of α and β Branching on the Rate of E2 Elimination and the Amount of Alkene Formed[a]

Substrate	Temperature, °C	Alkene, %	Rate × 10^5 of E2 Reaction	Reference
CH_3CH_2Br	55	0.9	1.6	108
$(CH_3)_2CHBr$	24	80.3	0.237	109
$(CH_3)_3CBr$	25	97	4.17	107
$CH_3CH_2CH_2Br$	55	8.9	5.3	105
$(CH_3)_2CHCH_2Br$	55	59.5	8.5	105

[a]The reactions were between the alkyl bromide and $^-$OEt The rate for isopropyl bromide was actually greater than that for ethyl bromide, if the temperature difference is considered. Neopentyl bromide, the next compound in the β-branching series, cannot be compared because it has no β-hydrogen and cannot give an elimination product without rearrangement.

so much, and usually the substitution product predominates. For example, solvolysis of *tert*-butyl bromide gave only 19% elimination[106] (cf. with Table 17.2). β Branching also increases the amount of E2 elimination with respect to S_N2 substitution (Table 17.2), not because elimination is faster, but because the S_N2 mechanism is so greatly slowed (p. 478). Under first-order conditions too, β branching favors elimination over substitution, probably for steric reasons.[107] However, E2 eliminations from compounds with charged leaving groups are slowed by β branching. This is related to Hofmann's rule (p. 1498). Electron-withdrawing groups in the β position not only increase the rate of E2 eliminations and shift the mechanisms toward the E1cB end of the spectrum, but also increase the extent of elimination as opposed to substitution.

Effect of the Attacking Base

1. *Effect on* E1 *versus* E2 *versus* E1cB. In the E1 mechanism, an external base is generally not required: The solvent acts as the base. Hence, when external bases are added, the mechanism is shifted toward E2. Stronger bases and higher base concentrations cause the mechanism to move toward the E1cB end of the E1-E2-E1cB spectrum.[110] However, weak bases in polar aprotic solvents can also be effective in elimination reactions with certain substrates (the E2C reaction). Normal E2 elimination has been accomplished with the following bases:[111] H_2O, NR_3, ^-OH, ^-OAc, ^-OR, ^-OAr, $^-NH_2$, CO_3^{2-},

[111]This list is from Banthorpe, D.V. *Elimination Reactions*; Elsevier, NY, ***1963***, p. 4.

$LiAlH_4$, I^-, CN^-, and organic bases. However, the only bases of preparative importance in the normal E2 reaction are OH^-, OR^-, and NH_2^-, usually in the conjugate acid as solvent, and certain amines. Weak bases effective in the E2C reaction are Cl^-, Br^- F^-, ^-OAc, and RS^-. These bases are often used in the form of their R_4N^+ salts.

2. *Effect on Elimination versus Substitution.* Strong bases not only benefit E2 as against E1, but also benefit elimination as against substitution. With a high concentration of strong base in a non-ionizing solvent, bimolecular mechanisms are favored and E2 predominates over S_N2. At low base concentrations, or in the absence of base altogether, in ionizing solvents, unimolecular mechanisms are favored, and the S_N1 mechanism predominates over the E1. In Chapter 10, it was pointed out that some species are strong nucleophiles, but weak bases (p. 490). The use of these obviously favors substitution, except that, as we have seen, elimination can predominate if polar aprotic solvents are used. It has been shown for the base cyanide that in polar aprotic solvents, the less the base is encumbered by its counterion in an ion pair (i.e., the freer the base), the more substitution is favored at the expense of elimination.[112]

Effect of the Leaving Group

1. *Effect on Reactivity.* The leaving groups in elimination reactions are similar to those in nucleophilic substitution. The E2 eliminations have been performed with the following groups: NR_3^+, PR_3^+, SR_2^+, OHR^+, SO_2R, OSO_2R, OCOR, OOH, OOR, NO_2,[113] F, Cl, Br, I, and CN (*not* OH_2^+). The E1 eliminations have been carried out with: NR_3^+, SR_2^+, OH_2^+, OHR^+, OSO_2R, OCOR, Cl, Br, I, and N_2^+.[114] However, the major leaving groups for preparative purposes are OH_2^+ (always by E1) and Cl, Br, I, and NR_3^+ (usually by E2).
2. *Effect on* E1 *versus* E2 *versus* E1cB. Better leaving groups shift the mechanism toward the E1 end of the spectrum, since they make ionization easier. This effect has been studied in various ways. One way already mentioned was a study of ρ values (p. 1495). Poor leaving groups and positively charged leaving groups shift the mechanism toward the E1cB end of the spectrum because the strong electron-withdrawing field effects increase the acidity of the β hydrogen.[115] The E2C reaction is favored by good leaving groups.
3. *Effect on Elimination versus Substitution.* As we have already seen (p. 1487), for first-order reactions the leaving group has nothing to do with the

[114]These lists are from Banthorpe, D.V. *Elimination Reactions*, Elsevier, NY, ***1963***, pp. 4, 7.
[115]For a discussion of leaving-group ability, see Stirling, C.J.M. *Acc. Chem. Res.* ***1979***, *12*, 198. See also, Varma, M.; Stirling, C.J.M. *J. Chem. Soc., Chem. Commun.* ***1981***, 553.

competition between elimination and substitution, since it is gone before the decision is made as to which path to take. However, where ion pairs are involved, this is not true, and results have been found where the nature of the leaving group does affect the product.[116] In second-order reactions, the elimination/substitution ratio is not greatly dependent on a halide leaving group, although there is a slight increase in elimination in the order $I > Br > Cl$. When OTs is the leaving group, there is usually much more substitution. For example, n-$C_{18}H_{37}Br$ treated with t-BuOK gave 85% elimination, while n-$C_{18}H_{37}OTs$ gave, under the same conditions, 99% substitution.[117] On the other hand, positively charged leaving groups increase the amount of elimination.

Effect of the Medium

1. *Effect of Solvent on* E1 *versus* E2 *versus* E1cB. With any reaction a more polar environment enhances the rate of mechanisms that involve ionic intermediates. For neutral leaving groups, it is expected that E1 and E1cB mechanisms will be aided by increasing polarity of solvent and by increasing ionic strength. With certain substrates, polar aprotic solvents promote elimination with weak bases (the E2C reaction).
2. *Effect of Solvent on Elimination versus Substitution.* Increasing polarity of solvent favors S_N2 reactions at the expense of E2. In the classical example, alcoholic KOH is used to effect elimination, while the more polar aqueous KOH is used for substitution. Charge-dispersal discussions, similar to those on p. 503,[118] only partially explain this. In most solvents, S_N1 reactions are favored over E1. The E1 reactions compete best in polar solvents that are poor nucleophiles, especially dipolar aprotic solvents.[119] A study made in the gas phase, where there is no solvent, has shown that when 1-bromopropane reacts with MeO^- only elimination takes place (no substitution) even with this primary substrate.[120]
3. *Effect of Temperature.* Elimination is favored over substitution by increasing temperature, whether the mechanism is first or second order.[121] The reason is that the activation energies of eliminations are higher than those of substitutions (because eliminations have greater changes in bonding).

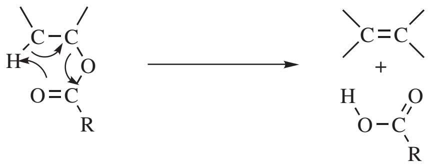
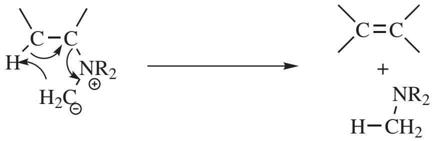
MECHANISMS AND ORIENTATION IN PYROLYTIC ELIMINATIONS

Mechanisms[122]

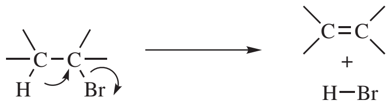
Several types of compound undergo elimination on heating, with no other reagent present. Reactions of this type are often run in the gas phase. The mechanisms are obviously different from those already discussed, since all those require a base (which may be the solvent) in one of the steps, and there is no base or solvent present in pyrolytic elimination. Two mechanisms have been found to operate. One involves a cyclic transition state, which may be four, five, or six membered. Examples of each size are



(17-4)

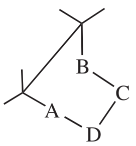


(17-8)



(17-13)

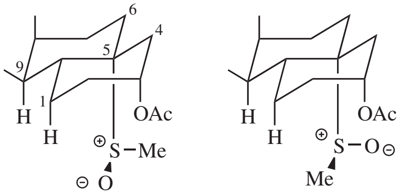
In this mechanism, the two groups leave at about the same time and bond to each other as they are doing so. The designation is E^i in the Ingold terminology and *cyclo*-$D_ED_NA_n$ in the IUPAC system. The elimination must be syn and, for the four- and five-membered transition states, the four or five atoms making up the ring must be coplanar. Coplanarity is not required for the six-membered transition state, since there is room for the outside atoms when the leaving atoms are staggered.



[122]For reviews, see Taylor, R., in Patai, S. *The Chemistry of Functional Groups, Supplement B*, pt. 2, Wiley, NY, ***1979***, pp. 860–914; Smith, G.G.; Kelly, F.W. *Prog. Phys. Org. Phys. Org. Chem.* ***1965***, *3*, 91. For reviews of mechanisms in pyrolytic eliminations of halides, see Egger, K.W.; Cocks, A.T., in Patai's. *The Chemistry of the Carbon-Halogen Bond*, pt. 2, Wiley, NY, ***1973***, pp. 677–745; Maccoll, A. *Chem. Rev.* ***1969***, *69*, 33.

As in the E2 mechanism, it is not necessary that the C–H and C–X bond be equally broken in the transition state. In fact, there is also a spectrum of mechanisms here, ranging from a mechanism in which C–X bond breaking is a good deal more advanced than C–H bond breaking to one in which the extent of bond breaking is virtually identical for the two bonds. Evidence for the existence of the E^i mechanism is

1. The kinetics are first order, so only one molecule of the substrate is involved in the reaction (i.e., if one molecule attacked another, the kinetics would be second order in substrate).[123]
2. Free-radical inhibitors do not slow the reactions, so no free-radical mechanism is involved.[124]
3. The mechanism predicts exclusive syn elimination, and this behavior has been found in many cases.[125] The evidence is inverse to that for the anti E2 mechanism and generally involves the following facts: (*1*) an erythro isomer gives a trans alkene and a threo isomer gives a cis alkene; (*2*) the reaction takes place only when a cis β hydrogen is available; (*3*) if, in a cyclic compound, a cis hydrogen is available on only one side, the elimination goes in that direction. Another piece of evidence involves a pair of steroid molecules. In 3β-acetoxy-(*R*)-5α-methylsulfinylcholestane (**26** shows rings A and B of this compound) and in 3β-acetoxy-(*S*)-5α-methylsulfinylcholestane (**27:** rings A and B), the *only* difference is the configuration of



26 **27**

oxygen and methyl about the sulfur. Yet pyrolysis of **26** gave only elimination to the 4-side (86% 4-ene), while **27** gave predominant elimination to the 6-side (65% 5-ene and 20% 4-ene).[126] Models show that interference from the 1- and 9-hydrogens causes the two groups on the sulfur to lie *in front of it* with respect to the rings, rather than behind it. Since the sulfur is chiral, this

[123]O'Connor, G.L.; Nace, H.R. *J. Am. Chem. Soc.* ***1953***, *75*, 2118.

[124]Barton, D.H.R.; Head, A.J.; Williams, R.J. *J. Chem. Soc.* ***1953***, 1715.

[125]In a few instances anti or nonstereoselective elimination has been found; this behavior is generally ascribed to the intervention of other mechanisms. For example, see Bordwell, F.G.; Landis, P.S. *J. Am. Chem. Soc.* ***1958***, *80*, 2450, 6383; Briggs, W.S.; Djerassi, C. *J. Org. Chem.* ***1968***, *33*, 1625; Smissman, E.E.; Li, J.P.; Creese, M.W. *J. Org. Chem.* ***1970***, *35*, 1352.

[126]Jones, D.N.; Saeed, M.A. *Proc. Chem. Soc.* ***1964***, 81. See also, Goldberg, S.I.; Sahli, M.S. *J. Org. Chem.* ***1967***, *32*, 2059.

means that in **26** the oxygen is near the 4-hydrogen, while in **27** it is near the 6-hydrogen. This experiment is compatible only with syn-elimination.[127]

4. The ^{14}C isotope effects for the Cope elimination (**17-9**) show that both the C–H and C–N bonds have been extensively broken in the transition state.[128]
5. Some of these reactions have been shown to exhibit negative entropies of activation, indicating that the molecules are more restricted in geometry in the transition state than they are in the starting compound.

Where a pyrolytic elimination lies on the mechanistic spectrum seems to depend mostly on the leaving group. When this is halogen, all available evidence suggests that in the transition state the C–X bond is cleaved to a much greater extent than the C–H bond, that is, there is a considerable amount of carbocation character in the transition state. This is in accord with the fact that a completely nonpolar four-membered cyclic transition state violates the Woodward–Hoffmann rules (see the similar case of **15-63**). Evidence for the carbocation-like character of the transition state when halide is the leaving group is that relative rates are in the order $I > Br > Cl$[129] (see p. 496), and that the effects of substituents on reaction rates are in accord with such a transition state.[130] Rate ratios for pyrolysis of some alkyl bromides at 320°C were ethyl bromide, 1; isopropyl bromide, 280; *tert*-butyl bromide, 78,000. Also, α-phenylethyl bromide had about the same rate as *tert*-butyl bromide. On the other hand, β-phenylethyl bromide was only slightly faster than ethyl bromide.[131] This indicates that C–Br cleavage was much more important in the transition state than C–H cleavage, since the incipient carbocation was stabilized by a alkyl and α-aryl substitution, while there was no incipient carbanion to be stabilized by β-aryl substitution. These substituent effects, as well as those for other groups, are very similar to the effects found for the S_N1 mechanism and thus in very good accord with a carbocation-like transition state.

For carboxylic esters, the rate ratios were much smaller,[132] although still in the same order, so that this reaction is closer to a pure E^i mechanism, although the transition state still has some carbocationic character. Other evidence for a greater initial C–O cleavage with carboxylic esters is that a series of 1-arylethyl acetates followed σ^+ rather than σ, showing carbocationic character at the 1 position.[133]

Perkin Trans. 2* ***1990***, 2187.

The extent of E1 character in the transition state increases in the following order of ester types: acetate < phenylacetate < benzoate < carbamate < carbonate.[134] Cleavage of xanthates (**17-5**), cleavage of sulfoxides (**17-12**), the Cope reaction (**17-9**), and reaction **17-8** are probably very close to straight E^i mechanisms.[135]

The second type of pyrolysis mechanism is completely different and involves free radicals. Initiation occurs by pyrolytic homolytic cleavage. The remaining steps may vary, and a few are shown

$$\text{Initiation} \quad R_2CHCH_2X \longrightarrow R_2CHCH_2\bullet + X\bullet$$
$$\text{Propagation} \quad R_2CHCH_2X + X\bullet \longrightarrow R_2\dot{C}CH_2X + HX$$
$$R_2\dot{C}CH_2X \longrightarrow CH_2 = CH_2X\bullet$$
$$\text{Termination (disproportionation)} \quad 2R_2\dot{C}CH_2X \longrightarrow R_2C = CH_2 + R_2CXCH_2X$$

Free-radical mechanisms are mostly found in pyrolyses of polyhalides and of primary monohalides,[136] although they also have been postulated in pyrolysis of certain carboxylic esters.[137] β-Elimination of tosyl radicals is known.[138] Much less is known about these mechanisms and we will not consider them further. Free-radical eliminations in solution are also known, but are rare.[139]

Orientation in Pyrolytic Eliminations

As in the E1-E2-E1cB mechanistic spectrum, Bredt's rule applies; and if a double bond is present, a conjugated system will be preferred, if sterically possible. Apart from these considerations, the following statements can be made for E^i eliminations:

1. In the absence of considerations mentioned below, orientation is statistical and is determined by the number of β hydrogens available (therefore *Hofmann's rule* is followed). For example, *sec*-butyl acetate gives 55–62%

[134]Taylor, R. *J. Chem. Soc. Perkin Trans. 2* ***1975***, 1025.

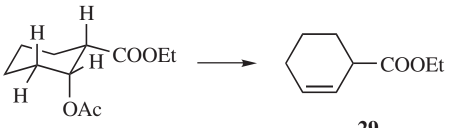
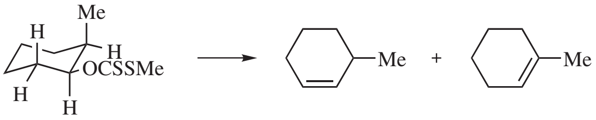
[139]For examples; see Kampmeier, J.A.; Geer, R.P.; Meskin, A.J.; D'Silva, R.M. *J. Am. Chem. Soc.* ***1966***, *88*, 1257; Kochi, J.K.; Singleton, D.M.; Andrews, L.J. *Tetrahedron* ***1968***, *24*, 3503; Boothe, T.E.; Greene Jr., J.L.; Shevlin, P.B. *J. Org. Chem.* ***1980***, *45*, 794; Stark, T.J.; Nelson, N.T.; Jensen, F.R. *J. Org. Chem.* ***1980***, *45*, 420; Kochi, J.K. *Organic Mechanisms and Catalysis*, Academic Press, NY, ***1978***, pp. 346–349; Kamimura, A.; Ono, N. *J. Chem. Soc., Chem. Commun.* ***1988***, 1278.

1-butene and 38–45% 2-butene,[140] which is close to the 3:2 distribution predicted by the number of hydrogens available.[141]

2. A cis β hydrogen is required. Therefore in cyclic systems, if there is a cis hydrogen on only one side, the double bond will go that way. However, when there is a six-membered transition state, this does not necessarily mean that the leaving groups must be cis to each other, since such transition states need not be completely coplanar. If the leaving group is axial, then the hydrogen obviously must be equatorial (and consequently cis to the leaving group), since the transition state cannot be realized when the groups are both axial. But if the leaving group is equatorial, it can form a transition state with a β hydrogen that is either axial (hence, cis) or equatorial (hence, trans). Thus **28**, in which the leaving group is most likely axial, does not form a double bond in the



28 **29** **(17-4)**



30 **(17-5)**

direction of the carbethoxyl group, even although that would be conjugated, because there is no equatorial hydrogen on that side. Instead it gives 100% **29**.[142] On the other hand, **30**, with an equatorial leaving group, gives ~50% of each alkene, even although, for elimination to the 1-ene, the leaving group must go off with a trans hydrogen.[143]

3. In some cases, especially with cyclic compounds, the more stable alkene forms and Zaitsev's rule applies. For example, menthyl acetate gives 35% of the Hofmann product and 65% of the Zaitsev, even although a cis β hydrogen is present on both sides and the statistical distribution is the other way. A similar result was found for the pyrolysis of menthyl chloride.[144]

4. There are also steric effects. In some cases, the direction of elimination is determined by the need to minimize steric interactions in the transition state or to relieve steric interactions in the ground state.

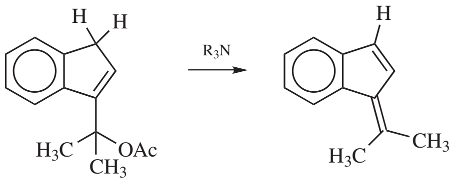
1,4 Conjugate Eliminations[145]

1,4-Eliminations of the type

$$\text{H-C-C=C-C-X} \longrightarrow \text{C=C-C=C}$$

are much rarer than conjugate additions (Chapter 15), but some examples are known.[146] One such is[147]



REACTIONS

First, we consider reactions in which a C=C or a C≡C bond is formed. From a synthetic point of view, the most important reactions for the formation of double bonds are **17-1** (usually by an E1 mechanism), **17-7**, **17-13**, and **17-22** (usually by an E2 mechanism), and **17-4**, **17-5**, and **17-9** (usually by an E^i mechanism). The only synthetically important method for the formation of triple bonds is **17-13**.[148] In the second section, we treat reactions in which C≡N bonds and C=N bonds are formed, and then eliminations that give C=O bonds and diazoalkanes. Finally, we discuss extrusion reactions.

REACTIONS IN WHICH C=C AND C≡C BONDS ARE FORMED

A. Reactions in which Hydrogen Is Removed from One Side

In **17-1–17-6**, the other leaving atom is oxygen. In **17-7–17-11**, it is nitrogen. For reactions in which hydrogen is removed from both sides, see **19-1–19-6**.

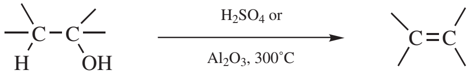
17-1 Dehydration of Alcohols

Hydro-hydroxy-elimination



Dehydration of alcohols can be accomplished in several ways. Both H_2SO_4 and H_3PO_4 are common reagents, but in many cases these lead to rearrangement products and to ether formation (**10-12**). If the alcohol can be evaporated, vapor-phase elimination over Al_2O_3 is an excellent method since side reactions are greatly reduced. This method has even been applied to such high-molecular-weight alcohols as 1-dodecanol.[149] Other metallic oxides (e.g., Cr_2O_3, TiO_2, WO_3) have also been used, as have been sulfides, other metallic salts, and zeolites. The presence of an electron-withdrawing group usually facilitates elimination of water, as in the aldol condensation (**16-35**). 2-Nitroalcohols, for example, give conjugated nitro compounds when heated with zeolite Y–Y.[150] Treating a 4-hydroxy lactam with DMAP (*N,N*-dimethylaminopyridine) and Boc anhydride leads to the conjugated lactam.[151] Elimination of serine derivatives to α-alkylidene amino acid derivatives was accomplished with $(EtO)_2POCl$.[152] Another method of avoiding side reactions is the conversion of alcohols to esters, and the pyrolysis of these (**17-4**–**17-6**). The ease of dehydration increases with α branching, and tertiary alcohols are dehydrated so easily with only a trace of acid that it sometimes happens even when the investigator desires otherwise. It may also be recalled that the initial alcohol products of many base-catalyzed condensations dehydrate spontaneously (Chapter 16) because the new double bond can be in conjugation with one already there. Many other dehydrating agents[153] have been used on occasion: P_2O_5, I_2, $ZnCl_2$, Ph_3BiBr_2/I_2,[154] PPh_3–I_2,[155] BF_3–etherate, DMSO, SiO_2–Cl/Me_3SiCl,[156] $KHSO_4$, anhydrous $CuSO_4$, and phthalic anhydride, among others. Secondary and tertiary alcohols can also be dehydrated, without rearrangements, simply on refluxing in HMPA.[157] With nearly all reagents, dehydration follows Zaitsev's rule.

[149]For example, see Spitzin, V.I.; Michailenko, I.E.; Pirogowa, G.N. *J. Prakt. Chem.* ***1964***, *[4] 25*, 160; Bertsch, H.; Greiner, A.; Kretzschmar, G.; Falk, F. *J. Prakt. Chem.* ***1964***, *[4] 25*, 184.

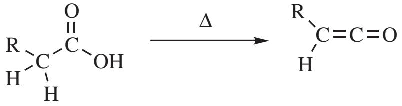
An exception involves the passage of hot alcohol vapors over thorium oxide at 350–450°C, under which conditions Hofmann's rule is followed,[158] and the mechanism is probably different. Cyclobutanol derivatives can be opened in the presence of a palladium catalyst. 2-Phenylbicyclo[3.2.0]octan-2-ol, for example, reacted with a catalytic amount of palladium acetate in the presence of pyridine and oxygen to give phenyl methylenecyclohexane ketone.[159]

Transition metals can induce the dehydration of certain alcohols. β-Hydroxy ketones are converted to conjugated ketones by treatment with $CeCl_3$ and NaI.[160] In the presence of a palladium complex, alkyl cyclopropanols undergo a dehydration reaction to give a conjugated ketone.[161] A δ-hydroxy-α,β-unsaturated aldehyde was converted to a dienyl aldehyde with a hafnium catalyst.[162] β-Hydroxy esters are converted to conjugated esters when treated with 2 equivalents of SmI_2.[163] The reaction of a β-hydroxy nitrile with methylmagneisum chloride[164] or with MgO[165] leads to a conjugated nitrile. In another variation of the dehydration reaction, vicinal bromohydrins are converted to alkenes upon treatment with In, $InCl_3$, and a palladium catalyst.[166] Chlorohydrins react similarly when treated with samarium, and then diiodomethane.[167]

Carboxylic acids can be dehydrated by pyrolysis, the product being a ketene:



Ketene itself is commercially prepared in this manner. Carboxylic acids have also been converted to ketenes by treatment with certain reagents, among them TsCl,[168] dicyclohexylcarbodiimide,[169] and 1-methyl-2-chloropyridinium iodide (*Mukaiyama's reagent*).[170] Analogously, amides can be dehydrated with P_2O_5, pyridine,

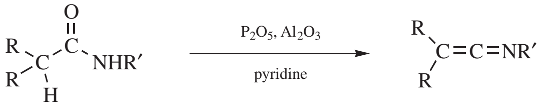
and Al_2O_3 to give ketenimines:[171]



There is no way in which dehydration of alcohols can be used to prepare triple bonds: *gem*-diols and vinylic alcohols are not normally stable compounds and *vic*-diols[172] give either conjugated dienes or lose only 1 equivalent of water to give an aldehyde or ketone. Dienes can be prepared, however, by heating alkynyl alcohols with triphenyl phosphine.[173]

When proton acids catalyze alcohol dehydration, the mechanism is E1.[174] The principal process involves conversion of ROH to ROH_2^+ and cleavage of the latter to R^+ and H_2O, although with some acids a secondary process probably involves conversion of the alcohol to an inorganic ester and ionization of *this* (illustrated for H_2SO_4):

$$\text{ROH} \xrightarrow{H_2SO_4} \text{ROSO}_2\text{OH} \longrightarrow \text{R}^+ + \text{HSO}_4^-$$

Note that these mechanisms are the reverse of those involved in the acid-catalyzed hydration of double bonds (**15-3**), in accord with the principle of microscopic reversibility. With anhydrides (e.g., P_2O_5, phthalic anhydride), as well as with some other reagents, such as HMPA,[175] it is likely that an ester is formed, and the leaving group is the conjugate base of the corresponding acid. In these cases, the mechanism can be E1 or E2. The mechanism with Al_2O_3 and other solid catalysts has been studied extensively, but is poorly understood.[176]

Magnesium alkoxides (formed by $ROH + Me_2Mg \rightarrow ROMgMe$) have been decomposed thermally, by heating at 195–340°C to give the alkene, CH_4, and MgO.[177] Syn-elimination is found and an E^i mechanism is likely. Similar decomposition of aluminum and zinc alkoxides has also been accomplished.[178,189]

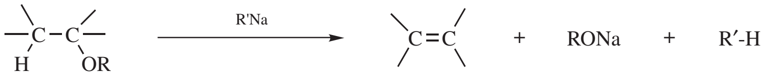
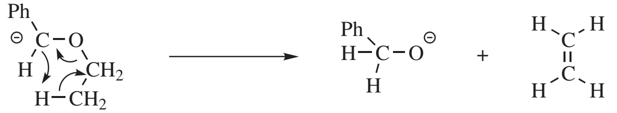
17-2 Cleavage of Ethers to Alkenes

Hydro-alkoxy-elimination



Alkenes can be formed by the treatment of ethers with very strong bases, such as alkylsodium or alkyllithium[179] compounds, sodium amide,[180] or LDA,[181] although there are side reactions with many of these reagents. The reaction is aided by electron-withdrawing groups in the β position, and, for example, $EtOCH_2CH(COOEt)_2$ can be converted to $CH_2{=}C(COOEt)_2$ without any base at all, but simply on heating.[182] *tert*-Butyl ethers are cleaved more easily than others. Several mechanisms are possible. In many cases, the mechanism is probably E1cB or on the E1cB side of the mechanistic spectrum,[183] since the base required is so strong, but it has been shown (by the use of $PhCD_2OEt$) that $PhCH_2OEt$ reacts by the five-membered E^i mechanism:[184] Propargylic benzyl ethers are converted to conjugated dienes by heating with a ruthenium catalyst.[185]



Ethers have also been converted to alkenes and alcohols by passing vapors over hot P_2O_5 or Al_2O_3 (this method is similar to **17-1**), but this is not a general reaction. Cyclic ethers, such as THF, react slowly with organolithium reagents with cleavage that produces a C=C unit.[186] Fragmentation of 2,5-dihydrofuran with ethylmagnesium chloride and a chiral zirconium catalyst leads to a chiral, homoallylic alcohol.[187] However, acetals can be converted to enol ethers (**31**) in this manner.

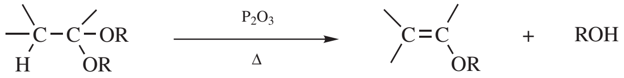
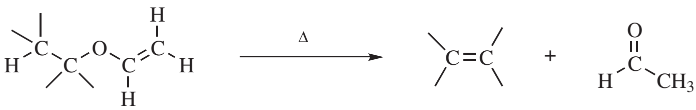
When ketals react with 2 equivalents of triisobutylaluminum, the product is a vinyl ether.[188]



31

This can also be done at room temperature by treatment with trimethylsilyl triflate and a tertiary amine[189] or with Me_3SiI in the presence of hexamethyldisilazane.[190]

Enol ethers can be pyrolyzed to alkenes and aldehydes in a manner similar to that of **17-4**

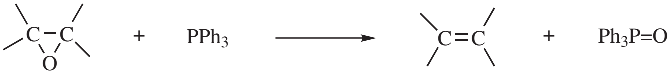


The rate of this reaction for R–O–CH=CH_2 increased in the order Et < *i*Pr < *t*-Bu.[191] The mechanism is similar to that of **17-4**.

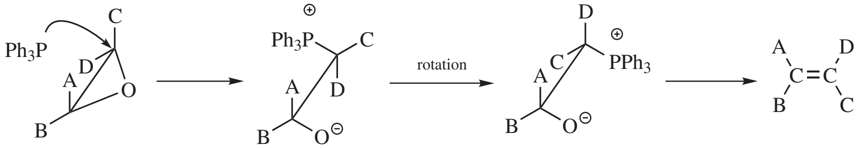
OS **IV**, 298, 404; **V**, 25, 642, 859, 1145; **VI**, 491, 564, 584, 606, 683, 948; **VIII**, 444.

17-3 The Conversion of Epoxides and Episulfides to Alkenes

***epi*-Oxy-elimination**



Epoxides can be converted to alkenes[192] by treatment with triphenylphosphine[193] or triethyl phosphite $P(OEt)_3$.[194] The first step of the mechanism is nucleophilic substitution (**10-35**), followed by a four-center elimination. Since inversion accompanies the substitution, the overall elimination is anti, that is, if two groups A and C are cis in the epoxide, they will be trans in the alkene:



Betaine

Alternatively, the epoxide can be treated with lithium diphenylphosphide, Ph_2PLi, and the product quaternized with methyl iodide.[195] Alkenes have also been obtained from epoxides by reaction with a large number of reagents,[196] among them Li in THF,[197] TsOH and NaI,[198] trimethylsilyl iodide,[199] PI_3,[200] F_3COOH–NaI,[201] SmI_2,[202] $Mo(CO)_6$, $TpReO_3$, where Tp is a pyrazolyl borate,[203] and the tungsten reagents mentioned in **17-18**. Some of these methods give syn elimination. Treatment of cyclooctane oxide with Ph_3P–$OPPh_3$ and NEt_3 gave cyclooctadiene.[204] Sodium amalgam with a cobalt–salen complex converted epoxides to alkenes.[205]

Epoxides can be converted to allylic alcohols[206] by treatment with several reagents, including *sec*-butyllithium,[207] *tert*-butyldimethylsilyl iodide,[208] and *i*Pr_2N-Li–*t*-BuOK (the *LIDAKOR reagent*).[209] Phenyllithium reacts with epoxides in the presence of lithium tetramethylpiperidide (LTMP) to give a trans alkene.[210] Sulfur ylids, such as $Me_2S{=}CH_2$, also convert epoxides to allylic alcohols.[211] Bromomethyl epoxides react with $InCl_3/NaBH_4$ to give an allylic alcohol.[212] α,β-Epoxy ketones are converted to conjugated ketones by treatment with NaI in acetone in the presence of Amberlyst 15,[213] or with 2.5 equivalents of SmI_2.[214] Cyclic epoxides are converted to conjugated dienes by heating with $(NMe_2)_2P({=}O)Cl$ and H_2O.[215]

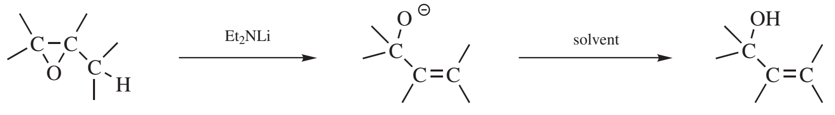
When an optically active reagent is used, optically active allylic alcohols can be produced from achiral epoxides.[216] Sparteine and *sec*-butyllithium generate a chiral base that leads to formation of chiral allylic alcohols.[217] Chiral diamines react with organolithium reagents to produce chiral bases that convert epoxides to allylic alcohols with good enantioselectivity.[218] Chiral diamines with a mixture of LDA and DBU (p. 1132) give similar results.[219]



Episulfides[220] can be converted to alkenes.[221] However, in this case the elimination is syn, so the mechanism cannot be the same as that for conversion of epoxides. The phosphite attacks sulfur rather than carbon. Among other reagents that convert episulfides to alkenes are Bu_3SnH,[222] certain rhodium complexes,[223] $LiAlH_4$[224] (this compound behaves quite differently with epoxides, see **19-35**), and meI.[225] The reaction of H_2S/PPh_3 and $MeReO_3$ converts episulfides to alkenes.[226] Episulfoxides can be converted to alkenes and sulfur monoxide simply by heating.[227]

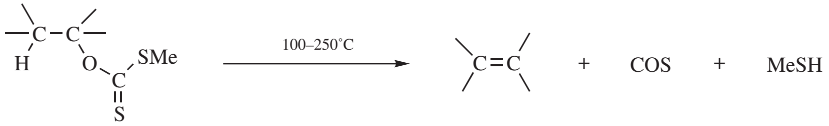
Direct elimination of a carboxylic acid to an alkene has been accomplished by heating in the presence of palladium catalysts.[228] Carboxylic esters in which the alkyl group has a β hydrogen can be pyrolyzed, most often in the gas phase, to give the corresponding acid and an alkene.[229] No solvent is required. Since rearrangement and other side reactions are few, the reaction is synthetically very useful and is often carried out as an indirect method of accomplishing **17-1**. The yields are excellent and the workup is easy. Many alkenes have been prepared in this manner. For higher alkenes (above $\sim C_{10}$) a better method is to pyrolyze the alcohol in the presence of acetic anhydride.[230]

The mechanism is E^i (see p. 1507). Lactones can be pyrolyzed to give unsaturated acids, provided that the six-membered transition state required for E^i reactions is available (it is not available for five- and six-membered lactones, but it is for larger rings[231]). Amides give a similar reaction, but require higher temperatures.

Allylic acetates give dienes when heated with certain palladium[232] or molybdenum[233] compounds.

OS **III**, 30; **IV**, 746; **V**, 235; **IX**, 293.

17-5 The Chugaev Reaction



Methyl xanthates are prepared by treatment of alcohols with NaOH and CS_2 to give RO–C(=S)–SNa, followed by treatment of this with methyl iodide.[234] Pyrolysis of the xanthate to give the alkene, COS, and the thiol is called the *Chugaev reaction*.[235] The reaction is thus, like **17-4**, an indirect method of accomplishing **17-2**. The temperatures required with xanthates are lower than with ordinary esters, which is advantageous because possible isomerization of the resulting alkene is minimized. The mechanism is E^i, similar to that of **17-4**. For a time there was doubt as to which sulfur atom closed the ring, but now there is much evidence, including

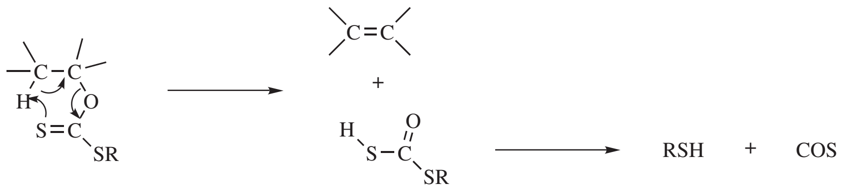
the study of ^{34}S and ^{13}C isotope effects, to show that it is the C=S sulfur:[236] In a structural variation of this reaction, heating a propargylic xanthate with 2,4,6-trimethylpyridinium trifluoromethyl sulfonate leads to formation of an alkene.[237]

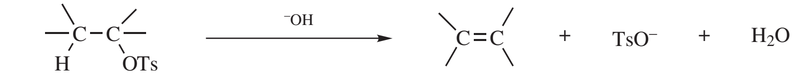


The mechanism is thus exactly analogous to that of **17-5**.

OS **VII**, 139.

17-6 Decomposition of Other Esters

Hydro-tosyloxy-elimination



Several types of inorganic ester can be cleaved to alkenes by treatment with bases. Esters of sulfuric, sulfurous, and other acids undergo elimination in solution by E1 or E2 mechanisms, as do tosylates and other esters of sulfonic acids.[238] It has been shown that bis(tetra-*n*-butylammonium) oxalate, $(Bu_4N^+)_2\ (COO^-)_2$, is an excellent reagent for inducing tosylates to undergo elimination rather than substitution.[239] Aryl sulfonates have also been cleaved without a base. Esters of 2-pyridinesulfonic acid and 8-quinolinesulfonic acid gave alkenes in high yields simply on heating, without a solvent.[240] Phosphonate esters have been cleaved to alkenes by treatment with Lawesson's reagent.[241] Esters of $PhSO_2OH$ and TsOH behaved similarly when heated in a dipolar aprotic solvent, such as Me_2SO or HMPA.[242]

Cleavage of quaternary ammonium hydroxides is the final step of the process known as *Hofmann exhaustive methylation or Hofmann degradation*.[243] In the first step, a primary, secondary, or tertiary amine is treated with enough methyl iodide to convert it to the quaternary ammonium iodide (**10-31**). In the second step, the iodide is converted to the hydroxide by treatment with silver oxide. In the cleavage step, an aqueous or alcoholic solution of the hydroxide is distilled, often under reduced pressure. The decomposition generally takes place at a temperature between 100 and 200°C. Alternatively, the solution can be concentrated to a syrup by distillation or freeze-drying.[244] When the syrup is heated at low pressures, the cleavage reaction takes place at lower temperatures than are required for the reaction in the ordinary solution, probably because the base (HO^- or RO^-) is less solvated.[245] The reaction has never been an important synthetic tool, but in the nineteenth century and the first part of the twentieth century, it saw much use in the determination of the structure of unknown amines, especially alkaloids. In many of these compounds, the nitrogen is in a ring, or even at a ring junction, and in such cases the alkene still contains nitrogen. Repetitions of the process are required to remove the nitrogen completely, as in the conversion of 2-methylpiperidine to 1,5-hexadiene by two rounds of exhaustive methylation followed by pyrolysis.

A side reaction involving nucleophilic substitution to give an alcohol (R_4N^+ $^-OH \rightarrow ROH + R_3N$) generally accompanies the normal elimination reaction,[246] but seldom causes trouble. However, when none of the four groups on the nitrogen has a β hydrogen, substitution is the only reaction possible. On heating Me_4N^+ ^-OH in water, methanol is obtained, although without a solvent the product is not methanol, but dimethyl ether.[247]

The mechanism is usually E2. Hofmann's rule is generally obeyed by acyclic and Zaitsev's rule by cyclohexyl substrates (p. 1498). In certain cases, where the molecule is highly hindered, a five-membered E^i mechanism, similar to that in **17-8**, has been shown to operate. That is, the hydroxide in these cases does not attract the β hydrogen, but instead removes one of the methyl hydrogens:

The obvious way to distinguish between this mechanism and the ordinary E2 mechanism is by the use of deuterium labeling. For example, if the reaction is carried out on a quaternary hydroxide deuterated on the β carbon ($R_2CDCH_2NMe_3^+$ ^-OH), the fate of the deuterium indicates the mechanism. If the E2 mechanism is in operation, the trimethylamine produced would contain no deuterium (which would be found only in the water). But if the mechanism is E^i, the amine would contain deuterium. In the case of the highly hindered compound $(Me_3C)_2CDCH_2NMe_3^+$ ^-OH, the deuterium did appear in the amine, demonstrating an Ei mechanism for this case.[248] With simpler compounds, the mechanism is E2, since here the amine was deuterium-free.[249]

When the nitrogen bears more than one group possessing a β hydrogen, which group cleaves? The Hofmann rule says that *within* a group the hydrogen on the least alkylated carbon cleaves. This tendency is also carried over to the choice of which group cleaves: thus ethyl with three β hydrogens cleaves more readily than any longer *n*-alkyl group, all of which have two β hydrogens. "The β hydrogen is removed most readily if it is located on a methyl group, next from RCH_2, and least readily from R_2CH."[250] In fact, the Hofmann rule as first stated[251] in 1851 applied only to which group cleaved, not to the orientation within a group; the latter could not have been specified in 1851, since the structural theory of organic compounds was not formulated until 1857–1860. Of course, the Hofmann rule (applied to which group cleaves *or* to orientation within a group) is superseded by conjugation possibilities. Thus $PhCH_2CH_2NMe_2Et^+$ ^-OH gives mostly styrene instead of ethylene.

Triple bonds have been prepared by pyrolysis of 1,2-bis(ammonium) salts.[252]

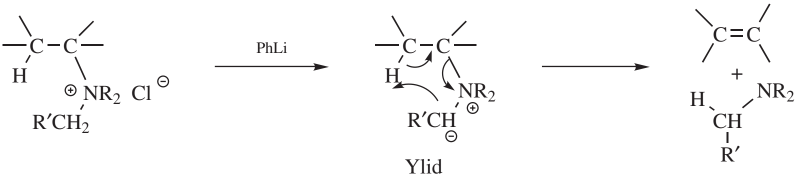
When quaternary ammonium halides are treated with strong bases (e.g., PhLi, KNH_2 in liquid NH_3[253]), an elimination can occur that is similar in products, although not in mechanism, to **17-7**. This is an alternative to **17-7** and is done on the quaternary ammonium halide, so that it is not necessary to convert this to the hydroxide. The mechanism is E^i:



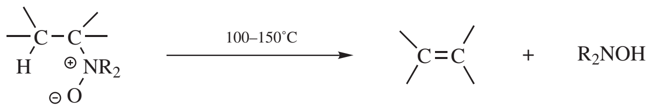
An α′ hydrogen is obviously necessary in order for the ylid to be formed. This type of mechanism is called α′,β elimination, since a β hydrogen is removed by the α′ carbon. The mechanism has been confirmed by labeling experiments similar to those described at **17-7**,[254] and by isolation of the intermediate ylids.[255] An important synthetic difference between this and most instances of **17-7** is that syn-elimination is observed here and anti-elimination in **17-7**, so products of opposite configuration are formed when the alkene exhibits cis–trans isomerism.

An alternative procedure that avoids the use of a very strong base is heating the salt with KOH in polyethylene glycol monomethyl ether.[256]

Benzotriazole has been shown to be a good leaving group for elimination reactions. The reaction of an allylic benzotriazole (3-benzotriazoyl-4-trimethylsilyl-1-butene) with *n*-butyllithium, and then an alkyl halide leads to an alkylated 1,3-diene upon heating.[257]

17-9 Cleavage of Amine Oxides

Hydro-(Dialkyloxidoammonio)-elimination



Cleavage of amine oxides to produce an alkene and a hydroxylamine is called the *Cope reaction* or *Cope elimination* (not to be confused with the Cope *rearrangement*, **18-32**). It is an alternative to **17-7** and **17-8**.[258] The reaction is usually

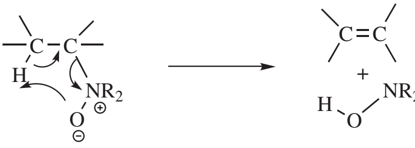
performed with a mixture of amine and oxidizing agent (see **19-29**) without isolation of the amine oxide. Because of the mild conditions side reactions are few, and the alkenes do not usually rearrange. The reaction is thus very useful for the preparation of many alkenes. A limitation is that it does not open six-membered rings containing nitrogen, although it does open rings of 5 and 7–10 members.[259] Rates of the reaction increase with increasing size of α and β-substituents.[260] The reaction can be carried out at room temperature in dry Me_2SO or THF.[261] The elimination is a stereoselective syn process,[262] and the five-membered E^i mechanism operates:



Almost all evidence indicates that the transition state must be planar. Deviations from planarity as in **17-4** (see p. 1507) are not found here, and indeed this is why six-membered heterocyclic nitrogen compounds do not react. Because of the stereoselectivity of this reaction and the lack of rearrangement of the products, it is useful for the formation of trans-cycloalkenes (eight-membered and higher). A polymer-bound Cope elimination reaction has been reported.[263]

OS **IV**, 612.

17-10 Pyrolysis of Keto-ylids

Hydro-(oxophosphoryl)-elimination

Phosphorus ylids are quite common (see **16-44**) and keto-phosphorus ylids [$RCOCH{=}PPh_3$] are also known. When these compounds are heating (flash vacuum pyrolysis, FVP) to > 500°C, alkynes are formed. Simple alkynes[264] can be formed as well as keto-alkynes[265] and en-ynes.[266] Rearrangement from ylids derived from tertiary amines an α-diazo ketones is also known.[267]

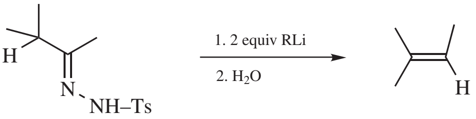
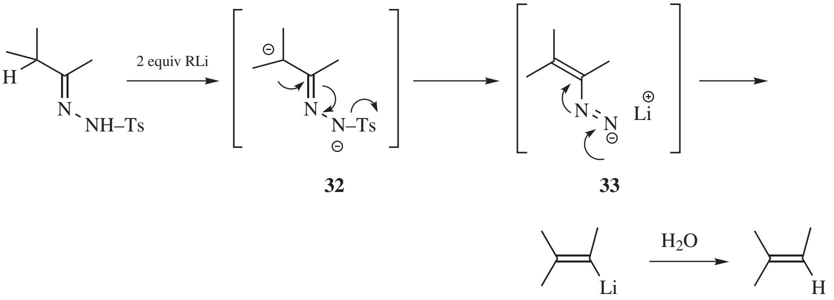
17-11 Decomposition of Toluene-*p*-sulfonylhydrazones



Treatment of the tosylhydrazone of an aldehyde or a ketone with a strong base leads to the formation of an alkene, the reaction being formally an elimination accompanied by a hydrogen shift.[268] The reaction (called the *Shapiro reaction*) has been applied to tosylhydrazones of many aldehydes and ketones. The most useful method synthetically involves treatment of the substrate with at least 2 equivalents of an organolithium compound[269] (usually MeLi) in ether, hexane, or tetramethylenediamine.[270] This procedure gives good yields of alkenes without side reactions and, where a choice is possible, predominantly gives the less highly substituted alkene. Tosylhydrazones of α,β-unsaturated ketones give conjugated dienes.[271] The mechanism[272] has been formulated as:



32 33

34

Evidence for this mechanism is (*1*) 2 equivalents of RLi are required; (*2*) the hydrogen in the product comes from the water and not from the adjacent carbon, as shown by deuterium labeling;[273] and (*3*) the intermediates **32–34** have been trapped.[274] This reaction, when performed in tetramethylenediamine, can be a synthetically useful method[275] of generating vinylic lithium compounds (**34**), which

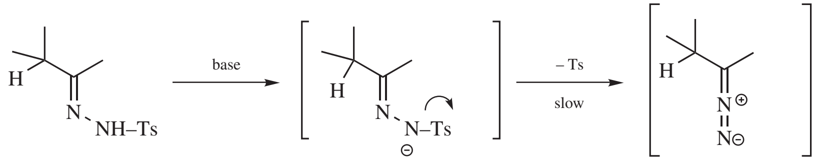
can be trapped by various electrophiles[276] such as D_2O (to give deuterated alkenes), CO_2 (to give α,β-unsaturated carboxylic acids, **16-30**), or DMF (to give α,β-unsaturated aldehydes, **16-82**). Treatment of *N*-aziridino hydrazones with LDA leads to alkenes with high cis selectivity.[277]

The reaction also takes place with other bases (e.g., LiH,[278] Na in ethylene glycol, NaH, $NaNH_2$) or with smaller amounts of RLi, but in these cases side reactions are common and the orientation of the double bond is in the other direction (to give the more highly substituted alkene). The reaction with Na in ethylene glycol is called the *Bamford–Stevens reaction*.[279] For these reactions two mechanisms are possible: a carbenoid and a carbocation mechanism.[280] The side reactions found are those expected of carbenes and carbocations. In general, the carbocation mechanism is chiefly found in protic solvents and the carbenoid mechanism in aprotic solvents. Both routes involve formation of a diazo compound (**35**) which in some cases can be isolated.



35

In fact, this reaction has been used as a synthetic method for the preparation of diazo compounds.[281] In the absence of protic solvents, **36** loses N_2, and hydrogen migrates, to give the alkene product. The migration of

hydrogen may immediately follow, or be simultaneous with, the loss of N_2. In a protic solvent, **35** becomes protonated to give the diazonium ion **36**, which loses N_2 to give the corresponding carbocation, that may then undergo elimination or give other reactions characteristic of carbocations. A diazo compound is an intermediate in the formation of alkenes by treatment of *N*-nitrosoamides with a rhodium(II) catalyst.[282]

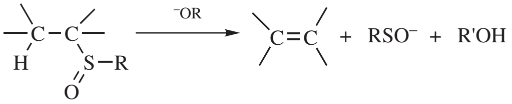
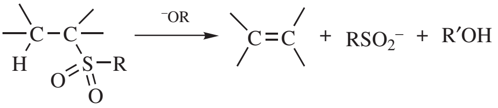
17-12 Cleavage of Sulfoxides, Selenoxides, and Sulfones

Hydro-alkylsulfinyl-elimination



Hydro-alkylsulfinyl-elimination



Sulfonium compounds ($–C–^+SR_2$) undergo elimination similar to that of their ammonium counterparts (**17-7** and **17-8**) in scope and mechanism but this reaction is not of great synthetic importance. These syn-elimination reactions are related to the Cope elimination (**17-9**) and the Hofmann elimination (**17-7**).[283]

Sulfones and sulfoxides[284] with a β hydrogen, on the other hand, undergo elimination on treatment with an alkoxide or, for sulfones,[285] even with hydroxide.[286] Sulfones also eliminate in the presence of an organolithium reagent and a palladium catalyst.[287] Mechanistically, these reactions belong on the E1-E2-E1cB spectrum.[288] Although the leaving groups are uncharged, the orientation follows Hofmann's rule, not Zaitsev's. Sulfoxides (but not sulfones) also undergo elimination

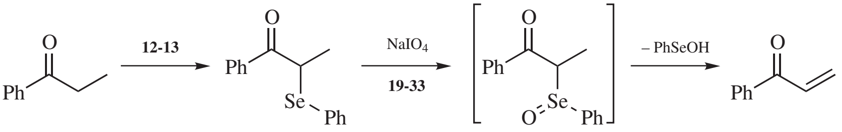
on pyrolysis at ~80°C in a manner analogous to **17-9**. The mechanism is also analogous, being the five-membered E^i mechanism with syn elimination.[289]

Selenoxides[290] and sulfinate esters R_2CH–CHR–SO–OMe[291] also undergo elimination by the E^i mechanism, the selenoxide reaction taking place at room temperature. The reaction with selenoxides has been extended to the formation of triple bonds.[292]

Both the selenoxide[293] and sulfoxide[294] reactions have been used in a method for the conversion of ketones, aldehydes, and carboxylic esters to their α,β-unsaturated derivatives (illustrated for the selenoxide).



Because of the mildness of the procedure, this is probably the best means of accomplishing this conversion. Treatment of ketones with LDA and then PhClS=N*t*-Bu leads to the conjugated ketone.[295] Allylic sulfoxides undergo 1,4-elimination to give dienes.[296] Ketones also react with hypervalent iodine cmpound in DMSO to give conjugated ketone.[297] In a simialr manner, keotnes are converted to conjugated keotnes by heating with HIO_5/I_2O_5 in DMSO.[298]

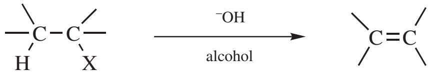
17-13 Dehydrohalogenation of Alkyl Halides

Hydro-halo-elimination



The elimination of HX from an alkyl halide is a very general reaction and can be accomplished with chlorides, fluorides, bromides, and iodides.[300] Hot alcoholic KOH is the most frequently used base, although stronger bases[301] ($^-$OR, $^-NH_2$, etc.) or weaker ones (e.g., amines) are used where warranted.[302] The bicyclic amidines 1,5-diazabicyclo[3.4.0]nonene-5 (DBN)[303] and 1,8-diazabicyclo[5.4.0]undecene-7 (DBU)[304] are good reagents for difficult cases.[305] Dehydrohalogenation with the non-ionic base $(Me_2N)_3P{=}N\text{-}P(NMe_2)_2{=}NMe$ is even faster.[306] Phase-transfer catalysis has been used with hydroxide as base.[307] As previously mentioned (p. 1495), certain weak bases in dipolar aprotic solvents are effective reagents for dehydrohalogenation. Among those most often used for synthetic purposes are LiCl or LiBr–$LiCO_3$ in DMF.[308] Dehydrohalogenation has also been effected by heating of the alkyl halide in HMPA with no other reagent present.[309] As in

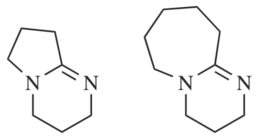
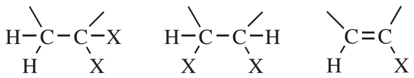
nucleophilic substitution (p. 496), the order of leaving group reactivity is I > Br > Cl > F.[310]



DBN DBU

Tertiary halides undergo elimination most easily. Eliminations of chlorides, bromides, and iodides follow Zaitsev's rule, except for a few cases where steric effects are important (for an example, see p. 1499). Eliminations of fluorides follow Hofmann's rule (p. 1500).

This reaction is by far the most important way of introducing a triple bond into a molecule.[311] Alkyne formation can be accomplished with substrates of the types:[312]



When the base is $NaNH_2$ 1-alkynes predominate (where possible), because this base is strong enough to form the salt of the alkyne, shifting any equilibrium between 1- and 2-alkynes. When the base is ^{-}OH or ^{-}OR, the equilibrium tends to be shifted to the internal alkyne, which is thermodynamically more stable. If another hydrogen is suitably located (e.g., $-CRH-CX_2-CH_2-$), allene formation can compete, although alkynes are usually more stable. 1,1,2-Trihalocyclopropanes are converted to alkynes by ring opening reactions.[313]

Dehydrohalogenation is generally carried out in solution, with a base, and the mechanism is usually E2, although the E1 mechanism has been demonstrated in some cases. However, elimination of HX can be accomplished by pyrolysis of the halide, in which case the mechanism is E^i (p. 1507) or, in some instances, the free-radical mechanism (p. 1510). Pyrolysis is normally performed without a catalyst at ~400°C. The pyrolysis reaction is not generally useful synthetically, because of its reversibility. Less work has been done on pyrolysis with a catalyst[314] (usually a metallic oxide or salt), but the mechanisms here are probably E1 or E2.

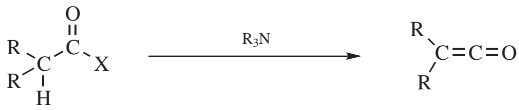
17-14 Dehydrohalogenation of Acyl Halides and Sulfonyl Halides

Hydro-halo-elimination



Ketenes can be prepared by treatment of acyl halides with tertiary amines[317] or with NaH and a crown ether.[318] The scope is broad, and most acyl halides possessing an α hydrogen give the reaction, but if at least one R is hydrogen, only the ketene dimer, not the ketene, is isolated. However, if it is desired to use a reactive ketene in a reaction with a given compound, the ketene can be generated *in situ* in the presence of the given compound.[319]

$$RCH_2SO_2Cl \xrightarrow{R_3N} [\,RCH{=}SO_2\,]_{\text{Sulfene}} \longrightarrow RCH{=}CHR \;+\; \text{Other products}$$

Closely related is the reaction of tertiary amines with sulfonyl halides that contain an a hydrogen. In this case, the initial product is the highly reactive sulfene, which cannot be isolated but reacts further to give products, one of which may be the alkene that is the dimer of RCH.[320] Reactions of sulfenes *in situ* are also common (e.g., see **16-48**).

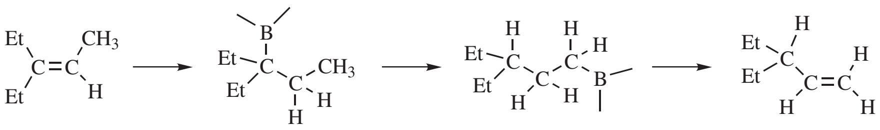
17-15 Elimination of Boranes

Hydro-boranetriyl-elimination

$$(R_2CH—CH_2)_3B \quad + \quad 3 \text{ 1-Decene} \rightleftharpoons 3\ R_2C{=}CH_2 \quad + \quad [CH_3(CH_2)_8CH_2]_3B$$

Trialkylboranes are formed from an alkene and BH_3 (**15-16**). When the resulting borane is treated with another alkene, an exchange reaction occurs.[321] This is an equilibrium process that can be shifted by using a large excess of alkene, by using an unusually reactive alkene, or by using an alkene with a higher boiling point than the displaced alkene and removing the latter by distillation. The reaction is useful for shifting a double bond in the direction opposite to that resulting from normal isomerization methods (**12-2**). This cannot be accomplished simply by treatment of a borane, such as **39**, with an alkene, because elimination in this reaction follows Zaitsev's rule: It is in the direction of the most stable alkene, and the product would be **38**, not **41**. However, if it is desired to convert **38** to **41**, this can be accomplished by converting **38** to **39**, isomerizing **39** to **40** (**18-11**) and then subjecting **40** to the exchange reaction with a higher boiling alkene (e.g., 1-decene), whereupon **41** is produced. In the usual isomerizations (**12-2**), **41** could be isomerized to **38**, but not the other way around. The reactions **39** → **40** and **40** → **41** proceed essentially without rearrangement. The mechanism is probably the reverse of borane addition (**15-16**).



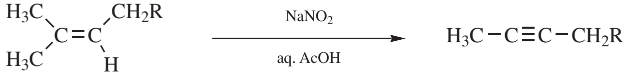
38 **39** **40** **41**

A similar reaction, but irreversible, has been demonstrated for alkynes.[322]

$$(R_2CH—CH_2)_3B \quad + \quad R'C{\equiv}CR' \longrightarrow 3\ R_2C{=}CH_2 \quad + \quad (R'CH{=}CR')_3B$$

17-16 Conversion of Alkenes to Alkynes

Hydro-methyl-elimination



Alkenes of the form shown lose the elements of methane when treated with sodium nitrite in acetic acid and water, to form alkynes in moderate-to-high yields.[323] The R may contain additional unsaturation, as well as OH, OR, OAc,

[321]Brown, H.C.; Bhatt, M.V.; Munekata, T.; Zweifel, G. *J. Am. Chem. Soc.* ***1967***, *89*, 567; Taniguchi, H. *Bull. Chem. Soc. Jpn.* ***1979***, *52*, 2942.

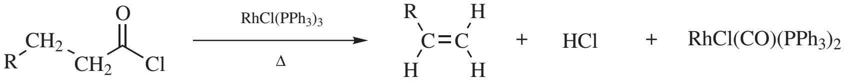
[323]Abidi, S.L. *Tetrahedron Lett.* ***1986***, *27*, 267; *J. Org. Chem.* ***1986***, *51*, 2687.

C=O, and other groups, but the $Me_2C{=}CHCH_2$ portion of the substrate is necessary for the reaction to take place. The mechanism is complex, beginning with a nitration that takes place with allylic rearrangement [$Me_2C{=}CHCH_2R \rightarrow H_2C{=}CMeCH(NO_2)CH_2R$], and involving several additional intermediates.[324] The CH_3 lost from the substrate appears as CO_2, as demonstrated by the trapping of this gas.[324]

1,1-Dibromoalkenes are converted to alkynes when treated with *n*-butyllithium.[325] This transformation is a modification of the *Fritsch–Buttenberg–Wiechell rearrangement*.[326] Vinyl sulfoxides that contain a leaving group, such as chloride on the double bond, react with *tert*-butyllithium to give a lithio alkyne, and hydrolysis leads to the final product, an alkyne.

17-17 Decarbonylation of Acyl Halides

Hydro-chloroformyl-elimination

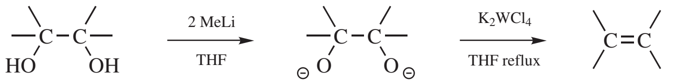


Acyl chlorides containing an a hydrogen are smoothly converted to alkenes, with loss of HCl and CO, on heating with chlorotris(triphenylphosphine)rhodium, with metallic platinum, or with certain other catalysts.[327] The mechanism probably involves conversion of RCH_2CH_2COCl to RCH_2CH_2–$RhCO(Ph_3P)_2Cl_2$ followed by a concerted syn elimination of Rh and H[328] (see also, **14-32** and **19-12**).

B. Reactions in Which Neither Leaving Atom Is Hydrogen

17-18 Deoxygenation of Vicinal Diols

Dihydroxy-elimination



vic-Diols can be deoxygenated by treatment of the dilithium dialkoxide with the tungsten halide (K_2WCl_6), or with certain other tungsten reagents, in refluxing THF.[329] Tetrasubstituted diols react most rapidly. The elimination is largely, but

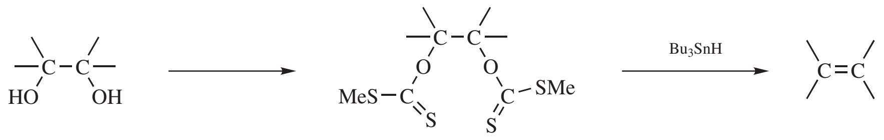
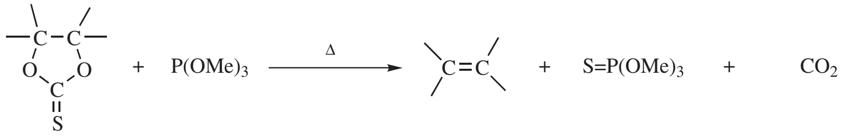
not entirely, syn. Several other methods have been reported,[330] in which the diol is deoxygenated directly, without conversion to the dialkoxide. These include treatment with titanium metal,[331] with TsOH–NaI,[332] and by heating with $CpReO_3$, where Cp is cyclopentadienyl.[333]

vic-Diols can also be deoxygenated indirectly, through sulfonate ester derivatives. For example, *vic*-dimesylates and *vic*-ditosylates have been converted to alkenes by treatment, respectively, with naphthalene-sodium[334] and with NaI in DMF.[335] In another procedure, the diols are converted to bisdithiocarbonates (bis xanthates), which undergo elimination (probably by a free-radical mechanism) when



treated with tri-*n*-butylstannane in toluene or benzene.[336] *vic*-Diols can also be deoxygenated through cyclic derivatives (**17-19**).

17-19 Cleavage of Cyclic Thionocarbonates



42

Cyclic thionocarbonates (**42**) can be cleaved to alkenes (the *Corey–Winter reaction*)[337] by heating with trimethyl phosphite[338] or other trivalent phosphorus compounds[339] or by treatment with bis(1,5-cyclooctadiene)nickel.[340] The

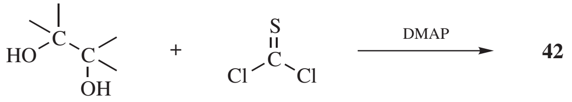
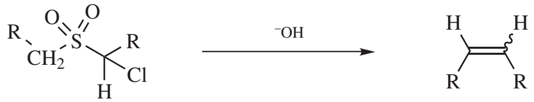
thionocarbonates can be prepared by treatment of 1,2-diols with thiophosgene and 4-dimethylaminopyridine (DMAP):[341]



The elimination is of course syn, so the product is sterically controlled. Alkenes that are not sterically favored can be made this way in high yield, (e.g., *cis*-$PhCH_2CH{=}CHCH_2Ph$).[342] Certain other five-membered cyclic derivatives of 1,2-diols can also be converted to alkenes.[343]

17-20 The Ramberg–Bäcklund Reaction

Ramberg–Bäcklund halosulfone transformation



The reaction of an α-halo sulfone with a base to give an alkene is called the *Ramberg–Bäcklund reaction*.[344] The reaction is quite general for α-halo sulfones with an α' hydrogen, despite the unreactive nature of α-halo sulfones in normal S_N2 reactions (p. 486). Halogen reactivity is in the order I > Br ≫ Cl. Phase-transfer catalysis has been used.[345] In general, mixtures of cis and trans isomers are obtained, but usually the less stable cis isomer predominates. The mechanism involves formation of an episulfone, and then elimination of SO_2. There is much

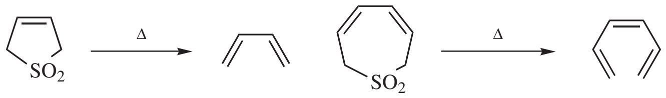
[345]Hartman, G.D.; Hartman, R.D. *Synthesis* ***1982***, 504.

evidence for this mechanism,[346] including the isolation of the episulfone intermediate,[347] and the preparation of episulfones in other ways and the demonstration that they give alkenes under the reaction conditions faster than the corresponding α-halo sulfones.[348] Episulfones synthesized in other ways (e.g., **16-48**) are reasonably stable compounds, but eliminate SO_2 to give alkenes when heated or treated with base.

If the reaction is run on the unsaturated bromo sulfones $RCH_2CH{=}CHSO_2CH_2Br$ (prepared by reaction of $BrCH_2SO_2Br$ with $RCH_2CH{=}CH_2$ followed by treatment with Et_3N), the dienes $RCH{=}CHCH{=}CH_2$ are produced in moderate-to-good yields.[349] The compound mesyltriflone $CF_3SO_2CH_2SO_2CH_3$ can be used as a synthon for the tetraion $^{2-}C{=}C^{2-}$. Successive alkylation (**10-67**) converts it to $CF_3SO_2CR^1R^2SO_2CHR^3R^4$ (anywhere from one to four alkyl groups can be put in), which, when treated with base, gives $R^1R^2C{=}CR^3R^4$.[350] The nucleofuge here is the $CF_3SO_2^-$ ion.



43 **44**

2,5-Dihydrothiophene-1,1-dioxides (**43**) and 2,17-dihydrothiepin-1,1-dioxides (**44**) undergo analogous 1,4- and 1,6-eliminations, respectively (see also, **17-36**). These are concerted reactions and, as predicted by the orbital-symmetry rules (p. 1207), the former[351] is a suprafacial process and the latter[352] an antarafacial process. The rules also predict that elimination of SO_2 from episulfones cannot take place by a concerted mechanism (except antarafacially, which is unlikely for such a small ring), and the evidence shows that this reaction occurs by a nonconcerted pathway.[353] The eliminations of SO_2 from **43** and **44** are examples of *cheletropic reactions*,[354] which are defined as reactions in which two σ bonds that terminate

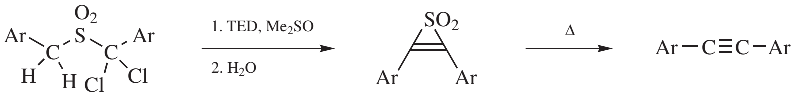
at a single atom (in this case the sulfur atom) are made or broken in concert.[355]



45 **46** **47**

α,α-Dichlorobenzyl sulfones (**45**) react with an excess of the base triethylenediamine (TED) in DMSO at room temperature to give 2,3-diarylthiiren-1,1-dioxides (**46**), which can be isolated.[356] Thermal decomposition of **46** gives the alkynes **47**.[357]

A Ramberg–Bäcklund-type reaction has been carried out on the α-halo *sulfides* ($ArCHClSCH_2Ar$), which react with *t*-BuOK and PPh_3 in refluxing THF to give the alkenes (ArCH=CHAr).[358] Cyclic sulfides lead to ring-contracted cyclic alkenes upon treatment with NCS in CCl_4 followed by oxidation with *m*-chloroperoxybenzoic acid.[359]

The Ramberg–Bäcklund reaction can be regarded as a type of extrusion reaction (see p. 1553).

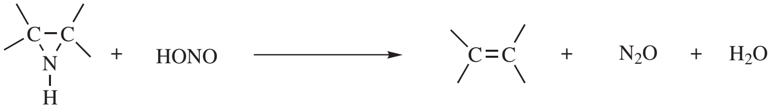
17-21 The Conversion of Aziridines to Alkenes

epi-Imino-elimination



Aziridines not substituted on the nitrogen atom react with nitrous acid to produce alkenes.[360] An *N*-nitroso compound is an intermediate (**12-50**); other reagents that produce such intermediates also give alkenes. The reaction is stereospecific: cis aziridines give cis alkenes and trans aziridines give trans alkenes.[361] Aziridines carrying *N*-alkyl substituents can be converted to alkenes by treatment with ferrous iodide[362] or with *m*-chloroperoxybenzoic acid.[363] An *N*-oxide intermediate

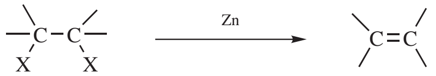
(**19-29**) is presumably involved in the latter case. *N*-Tosyl aziridines are converted to *N*-tosyl imines when treated with boron trifluoride.[364] 2-Tosylmethyl *N*-tosylaziridines react with Te^{2-} in the presence of Adogen 464 to give allylic *N*-tosyl amines.[365] 2-Halomethyl *N*-tosyl aziridines also react with indium metal in methanol to give *N*-tosyl allylic amines.[366]

17-22 Elimination of Vicinal Dihalides

Dihalo-elimination



Dehalogenation has been accomplished with many reagents, the most common being zinc, magnesium, and iodide ion.[367] Heating in HMPA is often enough to convert a *vic*-dibromide to an alkene.[368] Among reagents used less frequently have been phenyllithium, phenylhydrazine, $CrCl_2$, Na_2S in DMF,[369] and $LiAlH_4$.[370] Electrochemical reduction has also been used.[371] Treatment with In[372] or Sm[373] metal in CH_3OH, $InCl_3/NaBH_4$,[374] a Grignard reagent and Ni(dppe)Cl_2, (dppe = 1, 2-diphenylphosphinoethane),[375] nickel compounds with Bu_3SnH,[376] or SmI_2[377] leads to the alkene. Although the reaction usually gives good yields, it is not very useful because the best way to prepare *vic*-dihalides is by the addition of halogen to a double bond (**15-39**). One useful feature of this reaction is that there is no doubt about the *position* of the new double bond, so that it can be used to give double bonds exactly where they are wanted. For example, allenes, which are not easily prepared by other methods, can be prepared from X–C–CX_2–C–X or X–C–CX=C– systems.[378] Cumulenes

have been obtained from 1,4-elimination:

$$BrCH2{-}C{\equiv}C{-}CH_2Br \quad + \quad Zn \longrightarrow CH_2{=}C{=}C{=}CH_2$$

Cumulenes have also been prepared by treating alkynyl epoxides with boron trifluoride.[379] 1,4-Elimination of BrC–C=C–CBr has been used to prepare conjugated dienes C=C–C=C.[380] Allenes are formed by heating propargylic alcohols with arylboronic acids (p. 815) and a palladium catalyst.[381] Allenes are also formed from propargylic amines using a CuI and a palladium catalyst.[382]

The reaction of a vicinal dibromide with triethylamine and DMF with microwave irradiation leads to vinyl bromide.[383] Alkenes are formed from vicinal bromides by heating with iron in methanol[384] or samarium in the presence of TMSCl and a trace of water.[385] α,β-Dibromo amides are converted to conjugated amides upon photolysis in methanol.[386]

The reaction can be carried out for any combination of halogens, except where one is fluorine. Mechanisms are often complex and depend on the reagent and reaction conditions.[387] For different reagents, mechanisms involving carbocations, carbanions, and free-radical intermediates, as well as concerted mechanisms, have been proposed. When the reagent is zinc, anti stereospecificity has been observed in some cases,[388] but not in others.[389]

Note that geminal dibromo cyclopropanes (1,1-dibromocyclopropanes) are opened to conjugated dienes by heating to 500°C.[390]

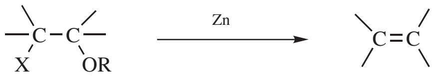
Ketenes can be prepared by dehalogenation of α-halo acyl halides with zinc or with triphenylphosphine.[391] The reaction generally gives good results when the two R groups are aryl or alkyl, but not when either one is hydrogen.[392]

OS **IV**, 348; **VIII**, 377.

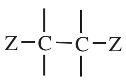
17-24 Elimination of a Halogen and a Hetero Group

Alkoxy-halo-elimination



The elimination of OR and halogen from β-halo ethers is called the *Boord reaction*. It can be carried out with zinc, magnesium, sodium, or certain other reagents.[393] The yields are high and the reaction is of broad scope. β-Halo acetals readily yield vinylic ethers

and 2 equivalents of SmI_2 in HMPA is effective.[394] Besides β-halo ethers, the reaction can also be carried out on compounds of the formula



where X is halogen and Z is OCOR, OTs,[395] NR_2,[396] or SR.[397] When X = Cl and Z = OAc, heating in THF with an excess of SmI_2 followed by treatment with dilute aq. HCl gives an alkene.[398] When Z = I and the other Z is an oxygen of an oxazolone (a carbamate unit), heating with indium metal in methanol leads to an allylic amine.[399] The Z group may also be OH, but then X is limited to Br and I.[400] Like **17-22**, this method ensures that the new double bond will be in a specific position.

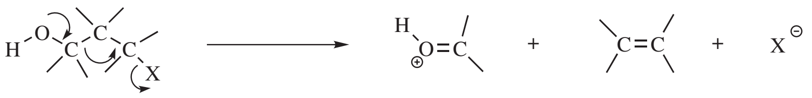
The fact that magnesium causes elimination in these cases limits the preparation of Grignard reagents from these compounds. It has been shown that treatment of β-halo ethers and esters with zinc gives nonstereospecific elimination,[401] so the mechanism was not E2. An E1cB mechanism was postulated because of the poor leaving-group ability of OR and OCOR. Bromohydrins can be converted to alkenes (elimination of Br, OH) in high yields by treatment with $LiAlH_4$–$TiCl_3$.[402]

OS **III**, 698, **IV**, 748; **VI**, 675.

FRAGMENTATIONS

When carbon is the positive leaving group (the electrofuge) in an elimination, the reaction is called *fragmentation*.[403] These processes occur on substrates of the form W–C–C–X, where X is a normal nucleofuge (e.g., halogen, OH_2^+, OTs, NR_3^+) and W is a positive-carbon electrofuge. In most of the cases, W is HO–C– or R_2N–C–, so that the positive charge on the carbon atom is stabilized by the unshared pair of the oxygen or nitrogen, for example,

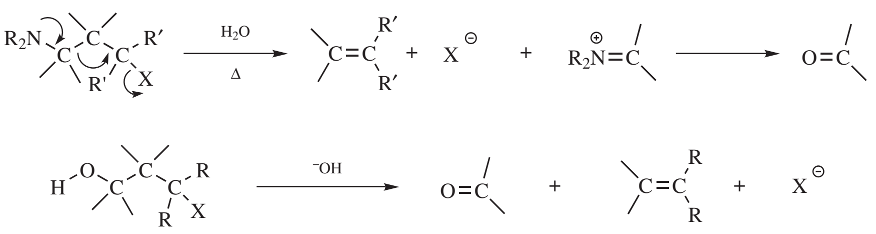


The mechanisms are mostly E1 or E2. We will discuss only a few fragmentations, since many are possible and not much work has been done on most of them. Reactions **17-25–17-28** and **17-30** may be considered fragmentations (see also **19-12** and **19-13**).

17-25 1,3-Fragmentation of γ-Amino, γ-Hydroxy Halides, and 1,3-Diols

Dialkylaminoalkyl-halo-elimination, and so on

Hydroxyalkyl-hydroxy-elimination

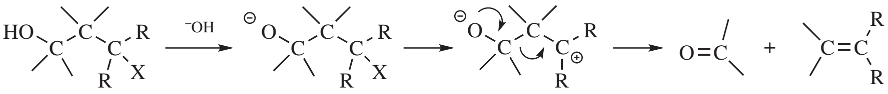


[401]House, H.O.; Ro, R.S. *J. Am. Chem. Soc.* ***1965***, *87*, 838.

[402]McMurry, J.E.; Hoz, T. *J. Org. Chem.* ***1975***, *40*, 3797.

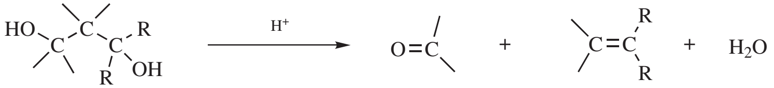
[403]For reviews, see Becker, K.B.; Grob, C.A., in Patai, S. *The Chemistry of Functional Groups, Supplement A*, pt. 2, Wiley, NY, ***1977***, pp. 653–723; Grob, C.A. *Angew. Chem. Int. Ed.* ***1969***, *8*, 535; Grob, C.A.; Schiess, P.W. *Angew. Chem. Int. Ed.* ***1967***, *6*, 1.

γ-Dialkylamino halides undergo fragmentation when heated with water to give an alkene and an iminium salt, which under the reaction conditions is hydrolyzed to an aldehyde or ketone (**16-2**).[404] γ-Hydroxy halides and tosylates are fragmented with base. In this instance, the base does not play its usual role in elimination reactions, but instead serves to remove a proton from the OH group, which enables the carbon leaving group to come off more easily:



The mechanism of these reactions is often E1. However, in at least some cases, an E2 mechanism operates.[405] It has been shown that stereoisomers of cyclic γ-amino halides and tosylates in which the two leaving groups can assume an antiperiplanar conformation react by the E2 mechanism, while those isomers in which the groups cannot assume such a conformation either fragment by the E1 mechanism or do not undergo fragmentation at all, but in either case give rise to side products characteristic of carbocations.[406]

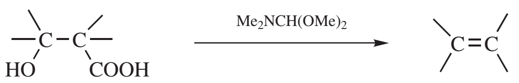
γ-Dialkylamino alcohols do not give fragmentation, since for ionization the OH group must be converted to OH_2^+ and this would convert NR_2 to NR_2H^+, which does not have the unshared pair necessary to form the double bond with the carbon.[407]



1,3-Diols in which at least one OH group is tertiary or is located on a carbon with aryl substituents can be cleaved by acid treatment.[408] The reaction is most useful synthetically when at least one of the OH groups is on a ring.[409]

17-26 Decarboxylation of β-Hydroxy Carboxylic Acids and of β-Lactones

Carboxy-hydroxy-elimination



An OH and a COOH group can be eliminated from β-hydroxy carboxylic acids by refluxing with excess dimethylformamide dimethyl acetal.[410] Mono-, di-, tri-, and tetrasubstituted alkenes have been prepared by this method in good yields.[411]

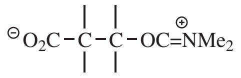
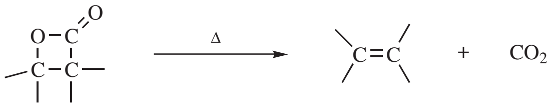
There is evidence that the mechanism involves E1 or E2 elimination from the zwitterionic intermediate[412]



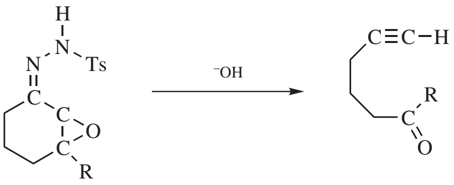
The reaction has also been accomplished[413] under extremely mild conditions (a few seconds at 0°C) with PPh_3 and diethyl azodicarboxylate EtOOC–N=N–COOEt.[414] In a related procedure, β-lactones undergo thermal decarboxylation to give alkenes in high yields. The reaction has been shown to be a stereospecific syn-elimination.[415] There is evidence that this reaction also involves a zwitterionic intermediate.[416]



There are no OS references, but see OS **VII**, 172, for a related reaction.

17-27 Fragmentation of α,β-Epoxy Hydrazones

Eschenmoser–Tanabe ring cleavage



Cyclic α,β-unsaturated ketones[417] can be cleaved by treatment with base of their epoxy tosylhydrazone derivatives to give acetylenic ketones.[418] The reaction can be applied to the formation of acetylenic aldehydes (R = H) by using the

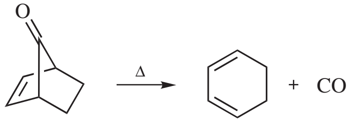
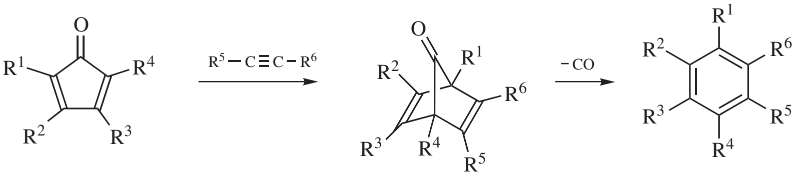
17-28 Elimination of CO and CO_2 from Bridged Bicyclic Compounds

***seco*-Carbonyl-1/4/elimination**



49

On heating, bicyclo[2.2.1]hept-2,3-en-17-ones (**49**) usually lose CO to give cyclohexadienes,[421] in a type of reverse Diels–Alder reaction. Bicyclo[2.2.1]hepta-dienones (**50**) undergo the reaction so readily (because of the



50

stability of the benzene ring produced) that they cannot generally be isolated. The parent **50** has been obtained at 10–15°K in an Ar matrix, where its spectrum could be studied.[422] Both **49** and **50** can be prepared by Diels–Alder reactions between a cyclopentadienone and an alkyne or alkene, so that this reaction is a useful method for the preparation of specifically substituted benzene rings and cyclohexadienes.[423]

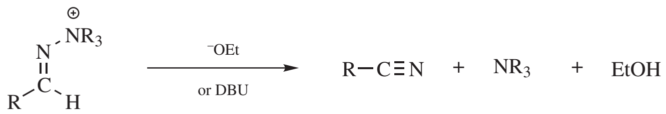
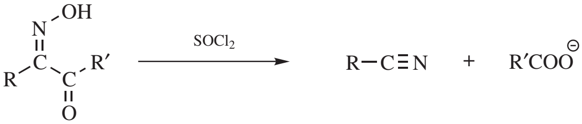
is effective for this transformation.[437] Microwave irradiation on EPZ-10[438] or sulfuric acid impregnated silica gel[439] gives the nitrile, as does microwave irradiation of an oxime with tetrachloropyridine on alumina.[440] Aldehydes can be converted to oximes *in situ* and microwave irradiation on alumina[441] or with ammonium acetate[442] gives the nitrile. Solvent-free reactions are known.[443] Electrochemical synthesis has also been used.[435] The reaction is most successful when the H and OH are anti. Various alkyl and acyl derivatives of aldoximes, for example, RCH=NOR, RCH=NOCOR, $RCH{=}NOSO_2Ar$, and so on, also give nitriles, as do chlorimines RCH=NCl (the latter with base treatment).[444] *N,N*-Dichloro derivatives of primary amines give nitriles on pyrolysis: $RCH_2NCl_2 \rightarrow RCN$.[445]



Quaternary hydrazonium salts (derived from aldehydes) give nitriles when treated with $^{-}$OEt[446] or DBU (p. 1132):[447] as do dimethylhydrazones, $RCH{=}NNMe_2$, when treated with Et_2NLi and HMPA.[448] All these are methods of converting aldehyde derivatives to nitriles. For the conversion of aldehydes directly to nitriles, without isolation of intermediates (see **16-16**).

Hydroxylamines that have an α-proton are converted to nitrones when treated with a manganese salen complex.[449]



Certain ketoximes can be converted to nitriles by the action of proton or Lewis acids.[450] Among these are oximes of α-diketones (illustrated above), α-keto acids,

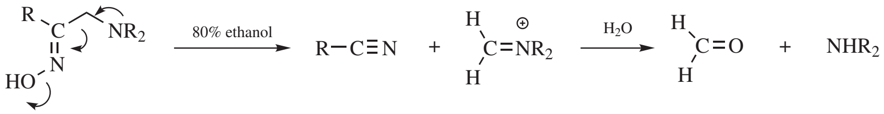
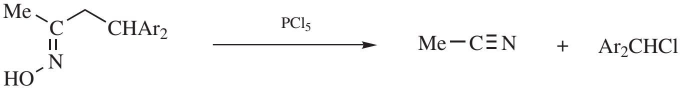
α-dialkylamino ketones, α-hydroxy ketones, β-keto ethers, and similar compounds.[451] These are fragmentation reactions, analogous to **17-25**. For example, α-dialkylamino ketoximes also give amines and aldehydes or ketones besides nitriles:[452]



The reaction that normally occurs on treatment of a ketoxime with a Lewis or proton acid is the Beckmann rearrangement (**18-17**); fragmentations are considered side reactions, often called "abnormal" or "second-order" Beckmann rearrangements.[453] Obviously, the substrates mentioned are much more susceptible to fragmentation than are ordinary ketoximes, since in each case an unshared pair is available to assist in removal of the group cleaving from the carbon. However, fragmentation is a side reaction even with ordinary ketoximes[454] and, in cases where a particularly stable carbocation can be cleaved, may be the main reaction:[455]



There are indications that the mechanism at least in some cases first involves a rearrangement and then cleavage. The ratio of fragmentation to Beckmann rearrangement of a series of oxime tosylates, RC(=NOTs)Me, was not related to the solvolysis rate but *was* related to the stability of R^+ (as determined by the solvolysis rate of the corresponding RCl), which showed that fragmentation did not take place in the rate-determining step.[456] It may be postulated then that the first step in the fragmentation and in the rearrangement is the same and that this is the rate-determining step. The product is determined in the second step:

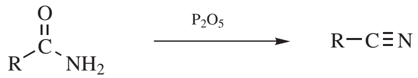
17-30 Dehydration of Unsubstituted Amides

***N,N*-Dihydro-*C*-oxo-bielimination**



Unsubstituted amides can be dehydrated to nitriles.[458] Phosphorous pentoxide is the most common dehydrating agent for this reaction, but many others, including $POCl_3$, PCl_5, CCl_4-Ph_3P,[459] HMPA,[460] LiCl with a zirconium catalyst,[461] $MeOOCNSO_2NEt_3$ (the Burgess reagent),[462] $Me_2N{=}CHCl^+$ Cl^-,[463] $AlCl_3$/KI/H_2O,[464] Bu_2SnO with microwave irradiation,[465] PPh_3/NCS,[466] triflic anhydride,[467] oxalyl chloride/DMSO/–78°C[468] (Swern conditions, see **19-3**), and $SOCl_2$ have also been used.[469] Heating an amide with paraformaldehyde and formic acid gives the nitrile.[470] Treatment with benzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate converts amides to nitriles.[471] It is possible to convert an acid to the nitrile, without isolation of the amide, by heating its ammonium salt with the dehydrating agent,[472] or by other methods.[473] Acyl halides can also be directly converted to nitriles by heating with sulfamide $(NH_2)_2SO_2$.[474] The reaction may be formally looked on as a β-elimination from the enol form of the amide RC(OH)=NH, in which case it is like **17-29**, except that H and OH have changed

places. In some cases, for example, with $SOCl_2$, the mechanism probably *is* through the enol form, with the dehydrating agent forming an ester with the OH group, for example, RC(OSOCl)=NH, which undergoes elimination by the E1 or E2 mechanism.[475] *N,N*-Disubstituted ureas give cyanamides ($R_2N–CO–NH_2 \rightarrow R_2N–CN$) when dehydrated with $CHCl_3$–NaOH under phase-transfer conditions.[476] Treatment of an amide with aqueous NaOH and ultrasound leads to the nitrile.[477]

N-Alkyl-substituted amides can be converted to nitriles and alkyl chlorides by treatment with PCl_5. This is called the *von Braun reaction* (not to be confused with the other von Braun reaction, **10-54**).

$$R'CONHR + PCl_5 \longrightarrow R'CN + RCl$$

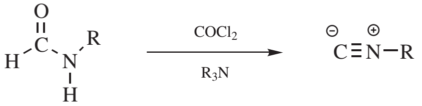
17-31 Conversion of *N*-Alkylformamides to Isonitriles (Isocyanides)

CN-Dihydro-*C*-oxo-bielimination



Isocyanides (isonitriles) can be prepared by elimination of water from *N*-alkylformamides[478] with phosgene and a tertiary amine.[479] Other reagents, among them TsCl in quinoline, $POCl_3$ and a tertiary amine,[480] $Me_2N{=}CHCl^+\ Cl^-$,[481] triflic anhydride-(*i*Pr)$_2$NEt,[482] PhOC(=S)Cl,[483] and $Ph_3P–CCl_4$-Et_3N[484] have also been employed. Formamides react with thionyl chloride (two sequential treatments) to give an intermediate that gives an isonitrile upon electrolysis in DMF with $LiClO_4$.[485]

A variation of this process uses carbodiimides,[486] which can be prepared by the dehydration of *N,N'*-disubstituted ureas with various dehydrating agents,[487] among

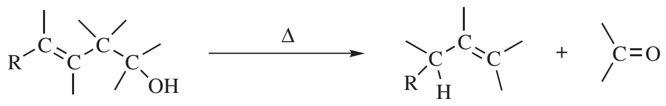
REACTIONS IN WHICH C=O BONDS ARE FORMED

Many elimination reactions in which C=O bonds are formed were considered in Chapter 16, along with their more important reverse reactions (also see, **12-40** and **12-41**).

17-32 Pyrolysis of β-Hydroxy Alkenes

***O*-Hydro-*C*-allyl-elimination**



When pyrolyzed, β-hydroxy alkenes cleave to give alkenes and aldehydes or ketones.[491] Alkenes produced this way are quite pure, since there are no side reactions. The mechanism has been shown to be pericyclic, primarily by observations that the kinetics are first order[492] and that, for ROD, the deuterium appeared in the allylic position of the new alkene.[493] This mechanism is the reverse of that for the oxygen analog of the ene synthesis (**16-54**). β-Hydroxyacetylenes react similarly to give the corresponding allenes and carbonyl compounds.[494] The mechanism is the same despite the linear geometry of the triple bonds.

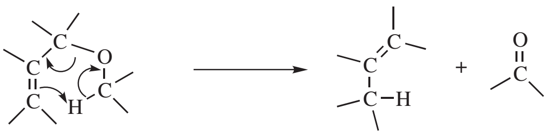
[494]Viola, A.; Proverb, R.J.; Yates, B.L.; Larrahondo, J. *J. Am. Chem. Soc.* ***1973***, *95*, 3609.

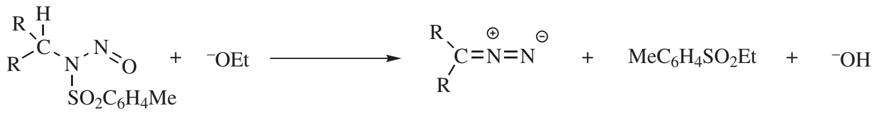
In a related reaction, pyrolysis of allylic ethers that contain at least one α hydrogen gives alkenes and aldehydes or ketones. The mechanism is also pericyclic[495]



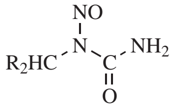
REACTIONS IN WHICH N=N BONDS ARE FORMED

17-33 Eliminations to Give Diazoalkanes

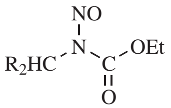
N-Nitrosoamine-diazoalkane transformation



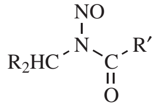
Various *N*-nitroso-*N*-alkyl compounds undergo elimination to give diazoalkanes.[496] One of the most convenient methods for the preparation of diazomethane involves base treatment of *N*-nitroso-*N*-methyl-*p*-toluenesulfonamide (illustrated above, with R = H).[497] However, other compounds commonly used are (base treatment is required in all cases):



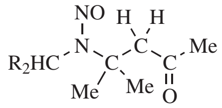
N-Nitroso-*N*-alkylureas



N-Nitroso-*N*-alkylcarbamates



N-Nitroso-*N*-alkyl amides



N-Nitroso-*N*-alkyl-4-amino-4-methyl-2-pentanone

All these compounds can be used to prepare diazomethane, although the sulfonamide, which is commercially available, is most satisfactory. *N*-Nitroso-*N*-methylcarbamate and *N*-nitroso-*N*-methylurea give good yields, but are highly irritating and carcinogenic.[498] For higher diazoalkanes the preferred substrates are nitrosoalkylcarbamates.

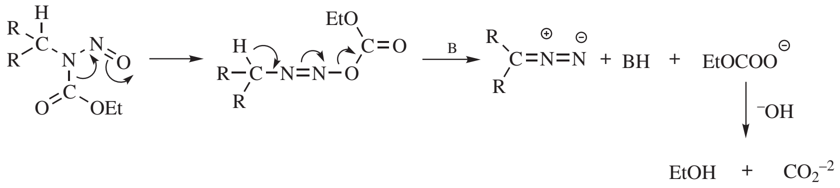
[498]Searle, C.E. *Chem. Br.* ***1970***, *6*, 5.

Most of these reactions probably begin with a 1,3 nitrogen-to-oxygen rearrangement, followed by the actual elimination (illustrated for the carbamate):



OS **II**, 165; **III**, 119, 244; **IV**, 225, 250; **V**, 351; **VI**, 981.

EXTRUSION REACTIONS

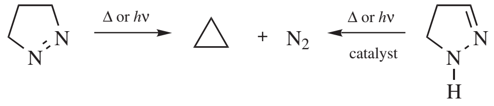
We consider an *extrusion reaction*[499] to be one in which an atom or group Y connected to two other atoms X and Z is lost from a molecule, leading to a product in which X is bonded directly to Z.

$$X{-}Y{-}Z \longrightarrow X{-}Z + Y$$

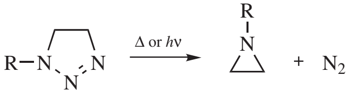
Reactions **14-32** and **17-20** also fit this definition. Reaction **17-28** does not fit the definition, but is often also classified as an extrusion reaction. An extrusibility scale has been developed, showing that the ease of extrusion of the common Y groups is in the order: –N=N– > –COO– > $-SO_2-$ > –CO–.[500]

17-34 Extrusion of N_2 from Pyrazolines, Pyrazoles, and Triazolines

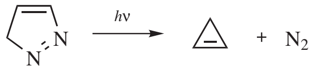
Azo-extrusion



52 **53**



54



55

[499]For a monograph, see Stark, B.P.; Duke, A.J. *Extrusion Reactions*, Pergamon, Elmsford, NY, ***1967***. For a review of extrusions that are photochemically induced, see Givens, R.S. *Org. Photochem.* ***1981***, *5*, 227.

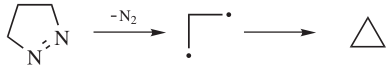
1-Pyrazolines (**52**) can be converted to cyclopropane and N_2 on photolysis[501] or pyrolysis.[502] The tautomeric 2-pyrazolines (**53**), which are more stable than **52** also give the reaction, but in this case an acidic or basic catalyst is required, the function of which is to convert **53** to **52**.[503] In the absence of such catalysts, **53** do not react.[504] In a similar manner, triazolines (**54**) are converted to aziridines.[505] Side reactions are frequent with both **52** and **54**, and some substrates do not give the reaction at all. However, the reaction has proved synthetically useful in many cases. In general, photolysis gives better yields and fewer side reactions than pyrolysis with both **52** and **54**. 3*H*-Pyrazoles[506] (**55**) are stable to heat, but in some cases can be converted to cyclopropenes on photolysis,[507] although in other cases other types of products are obtained.



There is much evidence that the mechanism[508] of the 1-pyrazoline reactions generally involves diradicals, although the mode of formation and detailed structure (e.g., singlet vs. triplet) of these radicals may vary with the substrate and reaction conditions. The reactions of the 3*H*-pyrazoles have been postulated to proceed through a diazo compound that loses N_2 to give a vinylic carbene.[509]

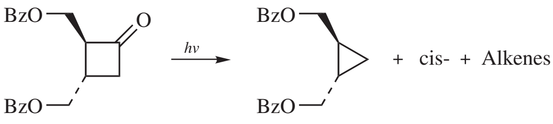
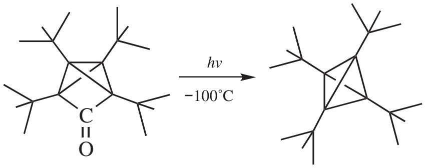
17-35 Extrusion of CO or CO_2

Carbonyl-extrusion



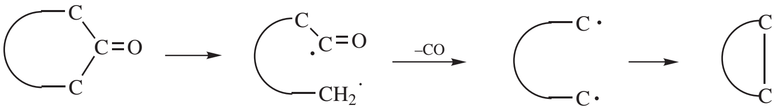
56 **57**

Although the reaction is not general, certain cyclic ketones can be photolyzed to give ring-contracted products.[510] In the example above, the cyclobutanone **56** was photolyzed to give **57**.[511] This reaction was used to synthesize tetra-*tert*-butyltetrahedrane, **58**.[512]

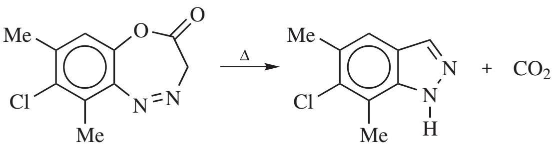


58

The mechanism probably involves a Norrish type I cleavage (p. 343), loss of CO from the resulting radical, and recombination of the radical fragments.



Certain lactones extrude CO_2 on heating or on irradiation, such as the pyrolysis of **59**.[513]



59

[510]For reviews of the reactions in this section, see Redmore, D.; Gutsche, C.D. *Adv. Alicyclic Chem.* ***1971***, *3*, 1, see pp. 91–107; Stark, B.P.; Duke, A.J. *Extrusion Reactions*, Pergamon, Elmsford, NY, ***1967***, pp. 47–71.

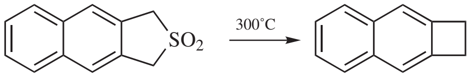
[513]Ried, W.; Wagner, K. *Liebigs Ann. Chem.* ***1965***, *681*, 45.

Decarboxylation of β-lactones (see **17-26**) may be regarded as a degenerate example of this reaction. Unsymmetrical diacyl peroxides RCO–OO–COR′ lose two molecules of CO_2 when photolyzed in the solid state to give the product RR′.[514] Electrolysis was also used, but yields were lower. This is an alternative to the Kolbe reaction (**11-34**) (see also **17-28** and **17-38**).

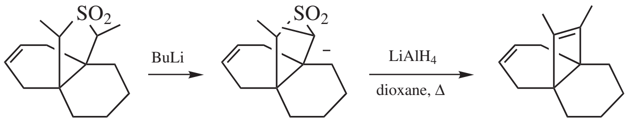
There are no OS references, but see OS **VI**, 418, for a related reaction.

17-36 Extrusion of SO_2

Sulfonyl-extrusion



In a reaction similar to **17-35**, certain sulfones, both cyclic and acyclic,[515] extrude SO_2 on heating or photolysis to give ring-contracted products.[516] An example is the preparation of naphtho(*b*)cyclobutene shown above.[517] In a different kind of reaction, five-membered cyclic sulfones can be converted to cyclobutenes by treatment with butyllithium followed by $LiAlH_4$,[518] for example,



This method is most successful when both the α and α' position of the sulfone bear alkyl substituents (see also **17-20**). Treating four-membered ring sultams with $SnCl_2$ led to aziridine products via loss of SO_2.[519]

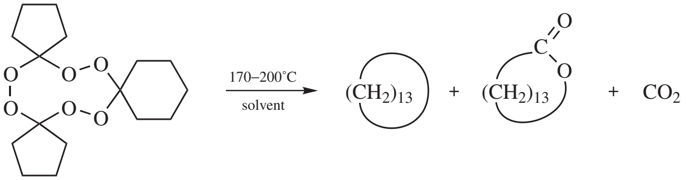
17-37 The Story Synthesis



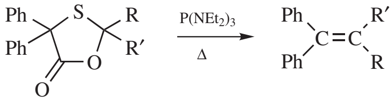
60

When cycloalkylidine peroxides (e.g., **60**) are heated in an inert solvent (e.g., decane), extrusion of CO_2 takes place; the products are the cycloalkane containing three carbon atoms less than the starting peroxide and the lactone containing two carbon atoms less[520] (the *Story synthesis*).[521] The two products are formed in comparable yields, usually ~15–25% each. Although the yields are low, the reaction is useful because there are not many other ways to prepare large rings. The reaction is versatile, having been used to prepare rings of every size from 8 to 33 members.

Both dimeric and trimeric cycloalkylidine peroxides can be synthesized[522] by treatment of the corresponding cyclic ketones with H_2O_2 in acid solution.[523] The trimeric peroxide is formed first and is subsequently converted to the dimeric compound.[524]

17-38 Alkene Synthesis by Twofold Extrusion

Carbon dioxide, thio-extrusion



61

4,4-Diphenyloxathiolan-5-ones (**61**) give good yields of the corresponding alkenes when heated with tris(diethylamino)phosphine.[525] This reaction is an

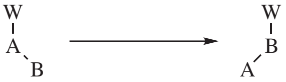
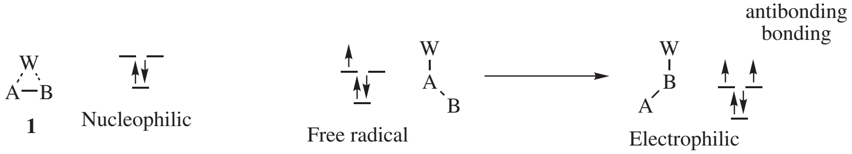
CHAPTER 18

Rearrangements

In a rearrangement reaction a group moves from one atom to another in the same molecule.[1] Most are migrations from an atom to an adjacent one (called 1,2-shifts), but some are over longer distances. The migrating group (W)



may move with its electron pair (these can be called *nucleophilic* or *anionotropic* rearrangements; the migrating group can be regarded as a nucleophile), without its electron pair (*electrophilic* or *cationotropic* rearrangements; in the case of migrating hydrogen, *prototropic* rearrangements), or with just one electron (free-radical rearrangements). The atom A is called the *migration origin* and B is the *migration terminus*. However, there are some rearrangements that do not lend themselves to neat categorization in this manner. Among these are those with cyclic transition states (**18-27–18-36**).



As we will see, nucleophilic 1,2-shifts are much more common than electrophilic or free-radical 1,2-shifts. The reason for this can be seen by a consideration of the transition states (or in some cases intermediates) involved. We represent the transition state or intermediate for all three cases by **1**, in which the two-electron

[1]For books, see de Mayo, P. *Rearrangements in Ground and Excited States*, 3 vols., Academic Press, NY, ***1980***; Stevens, T.S.; Watts, W.E. *Selected Molecular Rearrangements*, Van Nostrand-Reinhold, Princeton, NJ, ***1973***. For a review of many of these rearrangements, see Collins, C.J.; Eastham, J.F., in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, ***1966***, pp. 761–821. A–W bond overlaps with the orbital on atom B, which contains zero, one, and two electrons, in the case of nucleophilic, free-radical, and electrophilic migration, respectively. The overlap of these orbitals gives rise to three new orbitals, which have an energy relationship similar to those on p. 72 (one bonding and two degenerate antibonding orbitals). In a nucleophilic migration, where only two electrons are involved, both can go into the bonding orbital and **1** is a low-energy transition state; but in a free-radical or electrophilic migration, there are, respectively, three or four electrons that must be accommodated, and antibonding orbitals must be occupied. It is not surprising therefore that, when 1,2-electrophilic or free-radical shifts are found, the migrating group W is usually aryl or some other group that can accommodate the extra one or two electrons and thus effectively remove them from the three-membered transition state or intermediate (see **41** on p. 1577).

In any rearrangement, we can in principle distinguish between two possible modes of reaction: In one of these, the group W becomes completely detached from A and may end up on the B atom of a different molecule (*intermolecular* rearrangement); in the other W goes from A to B in the *same* molecule (*intramolecular* rearrangement), in which case there must be some continuing tie holding W to the A–B system, preventing it from coming completely free. Strictly speaking, only the intramolecular type fits our definition of a rearrangement, but the general practice, which is followed here, is to include under the title "rearrangement" all net rearrangements whether they are inter- or intramolecular. It is usually not difficult to tell whether a given rearrangement is inter- or intramolecular. The most common method involves the use of *crossover* experiments. In this type of experiment, rearrangement is carried out on a mixture of W–A–B and V–A–C, where V is closely related to W (say, methyl vs. ethyl) and B to C. In an intramolecular process only A–B–W and A–C–V are recovered, but if the reaction is intermolecular, then not only will these two be found, but also A–B–V and A–C–W.

MECHANISMS

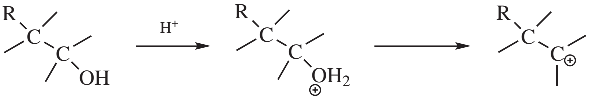
Nucleophilic Rearrangements[2]

Broadly speaking, such rearrangements consist of three steps, of which the actual migration is the second:

[2]For reviews, see Vogel, P. *Carbocation Chemistry*; Elsevier, NY, ***1985***, pp. 323–372; Shubin, V.G. *Top. Curr. Chem.* ***1984***, *116/117*, 267; Saunders, M.; Chandrasekhar, J.; Schleyer, P.v.R., in de Mayo, P. *Rearrangements in Ground and Excited States*, Vol. 1, Academic Press, NY, ***1980***, pp. 1–53; Kirmse, W. *Top. Curr. Chem.* ***1979***, *80*, 89. For reviews of rearrangements in vinylic cations, see Shchegolev, A.A.; Kanishchev, M.I. *Russ. Chem. Rev.* ***1981***, *50*, 553; Lee, C.C. *Isot. Org. Chem.* ***1980***, *5*, 1.

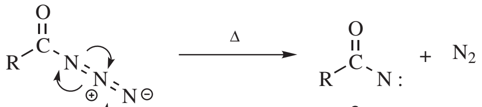
This process has been called the *Whitmore 1,2-shift*.[3] Since the migrating group carries the electron pair with it, the migration terminus B must be an atom with only six electrons in its outer shell (an open sextet). The first step therefore is creation of a system with an open sextet. Such a system can arise in various ways, but two of these are the most important:

1. *Formation of a Carbocation*. These can be formed in a number of ways (see p. 247), but one of the most common methods when a rearrangement is desired is the acid treatment of an alcohol to give **2** from an intermediate oxonium ion. These two steps are of course the same as the first two steps of the S_N1cA or the E1 reactions of alcohols.



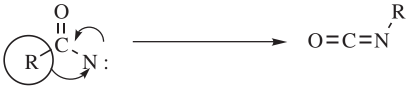
2

2. *Formation of a Nitrene*. The decomposition of acyl azides is one of several ways in which acyl nitrenes **3** are formed (see p. 293). After the migration has taken place, the atom at the migration origin (A) must necessarily have an open sextet. In the third step, this atom acquires an octet. In the case of carbocations, the most common third steps are combinations with a nucleophile (rearrangement with substitution) and loss of H^+ (rearrangement with elimination).



3

Although we have presented this mechanism as taking place in three steps, and some reactions do take place in this way, in many cases two or all three steps are simultaneous. For example, in the nitrene example above, as the R migrates, an electron pair from the nitrogen moves into the C–N bond to give a stable isocyanate, **4**.



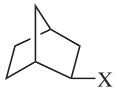
3 **4**

In this example, the second and third steps are simultaneous. It is also possible for the second and third steps to be simultaneous even when the "third" step involves more than just a simple motion of a pair of electrons. Similarly, there are many reactions in which the first two steps are simultaneous; that is, there is no actual formation of a species, such as **2** or **3**. In these instances, it may be said that

[3]It was first postulated by Whitmore, F.C. *J. Am. Chem. Soc.* ***1932***, *54*, 3274.

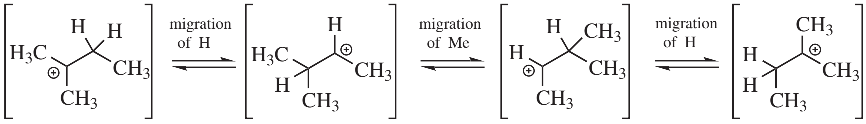
R assists in the removal of the leaving group, with migration of R and the removal of the leaving group taking place simultaneously. Many investigations have been carried out in attempts to determine, in various reactions, whether such intermediates as **2** or **3** actually form, or whether the steps are simultaneous (see, e.g., the discussions on pp. 1381, 1563), but the difference between the two possibilities is often subtle, and the question is not always easily answered.[4]

Evidence for this mechanism is that rearrangements of this sort occur under conditions where we have previously encountered carbocations: S_N1 conditions, Friedel–Crafts alkylation, and so on. Solvolysis of neopentyl bromide leads to rearrangement products, and the rate increases with increasing ionizing power of the solvent but is unaffected by concentration of base,[5] so that the first step is carbocation formation. The same compound under S_N2 conditions gave no rearrangement, but only ordinary substitution, though slowly. Thus with neopentyl bromide, formation of a carbocation leads only to rearrangement. Carbocations usually rearrange to more stable carbocations. Thus the direction of rearrangement is usually primary → secondary → tertiary. Neopentyl (Me_3CCH_2), neophyl ($PhCMe_2CH_2$), and norbornyl (e.g., **5**) type systems are especially prone to carbocation rearrangement reactions. It has been shown that the rate of migration increases with the degree of electron deficiency at the migration terminus.[6]



5

We have previously mentioned (p. 236) that stable tertiary carbocations can be obtained, in solution, at very low temperatures. The NMR studies have shown that when these solutions are warmed, rapid migrations of hydride and of alkyl groups take place, resulting in an equilibrium mixture of structures.[7] For example, the *tert*-pentyl cation (**5**)[8] equilibrates as follows:



6 **7** **7'** **6'**

[4]The IUPAC designations depend on the nature of the steps. For the rules, see Guthrie, R.D. *Pure Appl. Chem.* ***1989***, *61*, 23, 44–45.

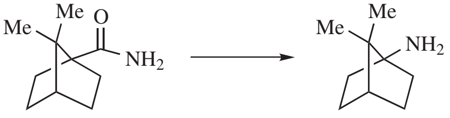
Carbocations that rearrange to give products of identical structure (e.g., **6** ⇌ **6'**,**7** ⇌ **7'**) are called *degenerate carbocations* and such rearrangements are *degenerate rearrangements*. Many examples are known.[9]

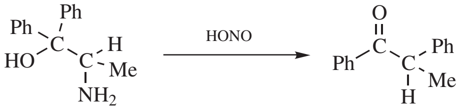
The Actual Nature of the Migration

Most nucleophilic 1,2-shifts are intramolecular. The W group does not become free, but always remains connected in some way to the substrate. Apart from the evidence from crossover experiments, the strongest evidence is that when the W group is chiral, the configuration is *retained* in the product. For example, (+)-PhCHMe-COOH was converted to (−)-$PhCHMeNH_2$ by the Curtius (**18-14**), Hofmann (**18-13**), Lossen (**18-15**), and Schmidt (**18-16**) reactions.[10] In these reactions, the extent of retention varied from 95.8 to 99.6%. Retention of configuration in the migrating group has been shown many times since.[11] Another experiment demonstrating retention was the



8 **9**

easy conversion of **8** to **9**.[11] Neither inversion nor racemization could take place at a bridgehead. There is much other evidence that retention of configuration usually occurs in W, and inversion never.[12] However, this is not the state of affairs at A and B. In many reactions, of course, the structure of W–A–B is such that the product has only one steric possibility at A or B or both, and in most of these cases nothing can be learned. But in cases where the steric nature of A or B can be investigated, the results are mixed. It has been shown that either inversion or racemization can occur at A or B. Thus the following conversion proceeded with inversion at B:[13]



(−) (+)

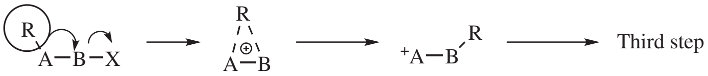
and inversion at A has been shown in other cases.[14] However, in many other cases, racemization occurs at A or B or both.[15] It is not always necessary for the product to have two steric possibilities in order to investigate the stereochemistry at A or B. Thus, in most Beckmann rearrangements (**18-17**), only the group trans (usually called *anti*) to the hydroxyl group migrates:

showing inversion at B.

This information tells us about the degree of concertedness of the three steps of the rearrangement. First consider the migration terminus B. If racemization is found at B, it is probable that the first step takes place before the second and that a positively charged carbon (or other sextet atom) is present at B:

With respect to B this is an S_N1-type process. If inversion occurs at B, it is likely that the first two steps are concerted, that a carbocation is *not* an intermediate, and that the process is S_N2-like:



10

In this case, participation by R assists in removal of X in the same way that neighboring groups do (p. 446). Indeed, R *is* a neighboring group here. The only difference is that, in the case of the neighboring-group mechanism of nucleophilic substitution, R never becomes detached from A, while in a rearrangement the bond between R and A is broken. In either case, the anchimeric assistance results in an increased rate of reaction. Of course, for such a process to take place, R must be in a favorable geometrical position (R and X antiperiplanar). Intermediate **10** may be a true intermediate or only a transition state, depending on what migrates. In certain cases of the S_N1-type process, it is possible for migration to take place with net retention of configuration at the migrating terminus because of conformational effects in the carbocation.[16]

We may summarize a few conclusions:

1. The S_N1-type process occurs mostly when B is a tertiary atom or has one aryl group and at least one other alkyl or aryl group. In other cases, the S_N2-type

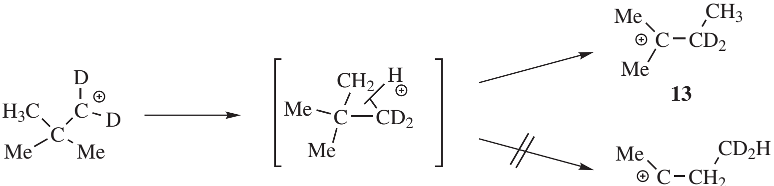
[14]See Meerwein, H.; van Emster, K. *Ber.* ***1920***, *53*, 1815; ***1922***, *55*, 2500; Meerwein, H.; Gérard, L. *Liebigs Ann. Chem.* ***1923***, *435*, 174.

[15]For example, see Winstein, S.; Morse, B.K. *J. Am. Chem. Soc.* ***1952***, *74*, 1133.

[16]Collins, C.J.; Benjamin, B.M. *J. Org. Chem.* ***1972***, *37*, 4358, and references cited therein.

process is more likely. Inversion of configuration (indicating an S_N2-type process) has been shown for a neopentyl substrate by the use of the chiral neopentyl-1-*d* alcohol.[17] On the other hand, there is other evidence that neopentyl systems undergo rearrangement by a carbocation (S_N1-type) mechanism.[18]

2. The question as to whether **10** is an intermediate or a transition state has been much debated. When R is aryl or vinyl, then **10** is probably an intermediate and the migrating group lends anchimeric assistance[19] (see p. 459 for resonance stabilization of this intermediate, when R is aryl). When R is alkyl, **10** is a protonated cyclopropane (edge- or corner-protonated; see p. 1026). There is much evidence that in simple migrations of a methyl group, the bulk of the products formed do not arise from protonated cyclopropane *intermediates*. Evidence for this statement has already been given (p. 467). Further evidence was obtained from experiments involving labeling.



11 **12** (hypothetical) **13** **14**

Rearrangement of the neopentyl cation labeled with deuterium in the 1 position (**11**) gave only *tert*-pentyl products with the label in the 3 position (derived from **13**), though if **12** were an intermediate, the cyclopropane ring could just as well cleave the other way to give *tert*-pentyl derivatives labeled in the 4 position (derived from **14**).[20] Another experiment that led to the same conclusion was the generation, in several ways, of $Me_3C^{13}CH_2^+$. In this case, the only *tert*-pentyl products isolated were labeled in C-3, that is, Me_2C^+–$^{13}CH_2CH_3$ derivatives; no derivatives of Me_2C^+–$CH_2{}^{13}CH_3$ were found.[21]

Although the bulk of the products are not formed from protonated cyclopropane intermediates, there is considerable evidence that at least in 1-propyl

[21]Karabatsos, G.J.; Orzech Jr., C.E.; Meyerson, S. *J. Am. Chem. Soc.* ***1964***, *86*, 1994.

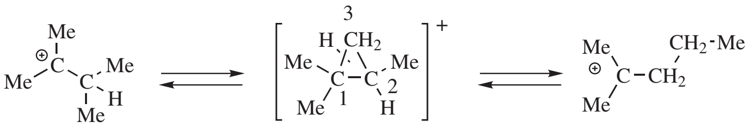
systems, a small part of the product can in fact arise from such intermediates.[22] Among this evidence is the isolation of 10–15% cyclopropanes (mentioned on p. 467). Additional evidence comes from propyl cations generated by diazotization of labeled amines ($CH_3CH_2CD_2^+$, $CH_3CD_2CH_2^+$, $CH_3CH_2{}^{14}CH_2^+$), where isotopic distribution in the products indicated that a small amount (~5%) of the product had to be formed from protonated cyclopropane intermediates, for example,[23]

$$CH_3CH_2CD_2NH_2 \xrightarrow{HONO} \sim 1\% \quad C_2H_4D\text{—}CHD\text{—}OH$$

$$CH_3CD_2CH_2NH_2 \xrightarrow{HONO} \sim 1\% \quad C_2H_4D\text{—}CHD\text{—}OH$$

$$CH_3CH_{2}{}_{14}CH_2NH_2 \xrightarrow{HONO} \sim 2\% \quad {}^{14}CH_3CH_2CH_2OH + \sim 2\% \quad CH_3{}^{14}CH_2CH_2OH$$

Even more scrambling was found in trifluoroacetolysis of 1-propyl-1-^{14}C-mercuric perchlorate.[24] However, protonated cyclopropane intermediates accounted for <1% of the products from diazotization of labeled isobutylamine[25] and from formolysis of labeled 1-propyl tosylate.[26]



15 16 17

It is likely that protonated cyclopropane transition states or intermediates are also responsible for certain non-1,2 rearrangements. For example, in super acid solution, the ions **15** and **17** are in equilibrium. It is not possible for these to interconvert solely by 1,2-alkyl or hydride shifts unless primary carbocations (which are highly unlikely) are intermediates. However, the reaction can be explained[27] by postulating that (in the forward reaction) it is the 1,2 bond

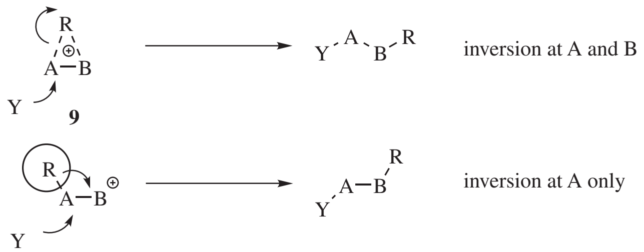
of the intermediate or transition state **16** that opens up rather than the 2,3 bond, which is the one that would open if the reaction were a normal 1,2-shift of a methyl group. In this case, opening of the 1,2 bond produces a tertiary cation, while opening of the 2,3 bond would give a secondary cation. (In the reaction **17** → **15**, it is of course the 1,3 bond that opens).

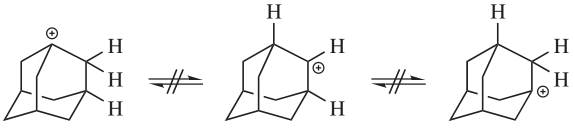
3. There has been much discussion of H as migrating group. There is no conclusive evidence that **10** in this case is or is not a true intermediate, although both positions have been argued (see p. 467).

The stereochemistry at the migration origin A is less often involved, since in most cases it does not end up as a tetrahedral atom; but when there is inversion here, there is an S_N2-type process at the beginning of the migration. This may or may not be accompanied by an S_N2 process at the migration terminus B:



In some cases, it has been found that, when H is the migrating species, the configuration at A may be *retained*.[28]

There is evidence that the configuration of the molecule may be important even where the leaving group is gone long before migration takes place. For example, the 1-adamantyl cation (**18**) does not equilibrate intramolecularly, even at temperatures up to 130°C,[29] though open-chain (e.g., **6** ⇄ **6'**) and cyclic tertiary



18 **18'**

carbocations undergo such equilibration at 0°C or below. On the basis of this and other evidence it has been concluded that for a 1,2-shift of hydrogen or methyl to proceed as smoothly as possible, the vacant *p* orbital of the carbon bearing the positive charge and the sp^3 orbital carrying the migrating group must be coplanar,[29] which is not possible for **18**.

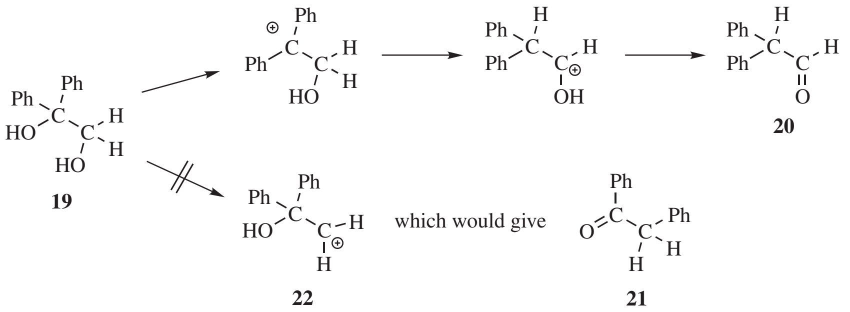
Migratory Aptitudes[30]

In many reactions, there is no question about which group migrates. For example, in the Hofmann, Curtius, and similar reactions there is only one possible migrating group in each molecule, and one can measure migratory aptitudes only by comparing the relative rearrangement rates of different compounds. In other instances, there are two or more potential migrating groups, but which migrates is settled by the geometry of the molecule. The Beckmann rearrangement (**18-17**) provides an example. As we have seen, only the group trans to the OH migrates. In compounds whose geometry is not restricted in this manner, there still may be eclipsing effects (see p. 1502), so that the choice of migrating group is largely determined by which group is in the right place in the most stable conformation of the molecule.[31] However, in some reactions, especially the Wagner–Meerwein (**18-1**) and the pinacol (**18-2**) rearrangements, the molecule may contain several groups that, geometrically at least, have approximately equal chances of migrating, and these reactions have often been used for the direct study of relative migratory aptitudes. In the pinacol rearrangement, there is the additional question of which OH group leaves and which does not, since a group can migrate only if the OH group on *the other* carbon is lost.

We deal with the second question first. To study this question, the best type of substrate to use is one of the form $R_2C(OH)-CR'_2(OH)$, since the only thing that determines migratory aptitude is which OH group comes off. Once the OH group is gone, the migrating group is determined. As might be expected, the OH that leaves is the one whose loss gives rise to the more stable carbocation. Thus 1,1-diphenylethanediol (**19**) gives diphenylacetaldehyde (**20**), not phenylacetophenone (**21**). Obviously, it does not matter in this case whether phenyl has a greater



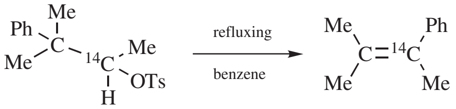
inherent migratory aptitude than hydrogen or not. Only the hydrogen can migrate because **22** is not formed. As we know, carbocation stability is enhanced by

[30]For discussions, see Koptyug, V.A.; Shubin, V.G. *J. Org. Chem. USSR* ***1980***, *16*, 1685; Wheland, G.W. *Advanced Organic Chemistry*, 3rd ed., Wiley, NY, ***1960***, pp. 573–597.

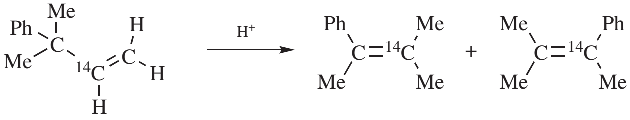
[31]For a discussion, see Cram, D.J., in Newman, M.S. *Steric Effects in Organic Chemistry*, Wiley, NY, ***1956***, pp. 270–276. For an interesting example, see Nickon, A.; Weglein, R.C. *J. Am. Chem. Soc.* ***1975***, *97*, 1271.

groups in the order aryl > alkyl > hydrogen, and this normally determines which side loses the OH group. However, exceptions are known, and which group is lost may depend on the reaction conditions (e.g., see the reaction of **53**, p. 1586).

In order to answer the question about inherent migratory aptitudes, the obvious type of substrate to use (in the pinacol rearrangement) is $R'RC(OH)-C(OH)RR'$, since the same carbocation is formed no matter which OH leaves, and it would seem that a direct comparison of the migratory tendencies of R and R′ is possible. On closer inspection, however, we can see that several factors are operating. Apart from the question of possible conformational effects, already mentioned, there is also the fact that whether the group R or R′ migrates is determined not only by the relative inherent migrating abilities of R and R′, but also by whether the group that does *not* migrate is better at stabilizing the positive charge that will now be found at the migration origin.[32] Thus, migration of R gives rise to the cation $R'C^+(OH)CR_2R'_2$, while migration of R' gives the cation $R^+C(OH)CRR'_2$, and these cations have different stabilities. It is possible that in a given case R might be found to migrate less than R′, not because it actually has a lower inherent migrating tendency, but because it is much better at stabilizing the positive charge. In addition to this factor,



23



24

migrating ability of a group is also related to its capacity to render anchimeric assistance to the departure of the nucleofuge. An example of this effect is the finding that in the decomposition of tosylate **23** only the phenyl group migrates, while in acid treatment of the corresponding alkene **24**, there is competitive migration of both methyl and phenyl (in these reactions ^{14}C labeling is necessary to determine which group has migrated).[33] Both **23** and **24** give the same carbocation; the differing results must be caused by the fact that in **23** the phenyl group can assist the leaving group, while no such process is possible for **24**. This example clearly illustrates the difference between migration to a relatively

[32]For example, see McCall, M.J.; Townsend, J.M.; Bonner, W.A. *J. Am. Chem. Soc.* ***1975***, *97*, 2743; Brownbridge, P.; Hodgson, P.K.G.; Shepherd, R.; Warren, S. *J. Chem. Soc. Perkin Trans. 1* ***1976***, 2024.
[33]Grimaud, J.; Laurent, A. *Bull. Soc. Chim. Fr.* ***1967***, 3599.

free terminus and one that proceeds with the migrating group lending anchimeric assistance.[34]

It is not surprising therefore that clear-cut answers as to relative migrating tendencies are not available. More often than not migratory aptitudes are in the order aryl > alkyl, but exceptions are known, and the position of hydrogen in this series is often unpredictable. In some cases, migration of hydrogen is preferred to aryl migration; in other cases, migration of alkyl is preferred to that of hydrogen. Mixtures are often found and the isomer that predominates often depends on conditions. For example, the comparison between methyl and ethyl has been made many times in various systems, and in some cases methyl migration and in others ethyl migration has been found to predominate.[35] However, it can be said that among aryl migrating groups, electron-donating substituents in the para and meta positions increase the migratory aptitudes, while the same substituents in the ortho positions decrease them. Electron-withdrawing groups decrease migrating ability in all positions. The following are a few of the relative migratory aptitudes determined for aryl groups by Bachmann and Ferguson:[36] *p*-anisyl, 500; *p*-tolyl, 15.7; *m*-tolyl, 1.95; phenyl, 1.00; *p*-chlorophenyl, 0.7; *o*-anisyl, 0.3. For the *o*-anisyl group, the poor migrating ability probably has a steric cause, while for the others there is a fair correlation with activation or deactivation of electrophilic aromatic substitution, which is what the process is with respect to the benzene ring. It has been reported that at least in certain systems acyl groups have a greater migratory aptitude than alkyl groups.[37]

Memory Effects[38]

Solvolysis of the endo bicyclic compound **25** (X = ONs, p. 497, or Br) gave mostly the bicyclic allylic alcohol, **28**, along with a smaller amount of the tricyclic alcohol **32**, while solvolysis of the exo isomers, **29**, gave mostly **32**, with smaller amounts of **28**.[39] Thus the two isomers gave entirely different ratios of products, although

[34]A number of studies of migratory aptitudes in the dienone-phenol rearrangement (**18-5**) are in accord with the above. For a discussion, see Fischer, A.; Henderson, G.N. *J. Chem. Soc., Chem. Commun.* ***1979***, 279, and references cited therein. See also, Palmer, J.D.; Waring, A.J. *J. Chem. Soc. Perkin Trans. 2* ***1979***, 1089; Marx, J.N.; Hahn, Y.P. *J. Org. Chem.* ***1988***, *53*, 2866.

[35]For examples, see Cram, D.J.; Knight, J.D. *J. Am. Chem. Soc.* ***1952***, *74*, 5839; Stiles, M.; Mayer, R.P. *J. Am. Chem. Soc.* ***1959***, *81*, 1497; Heidke, R.L.; Saunders, Jr., W.H. *J. [38]For a review, see Berson, J.A. *Angew. Chem. Int. Ed.* ***1968***, *7*, 779.

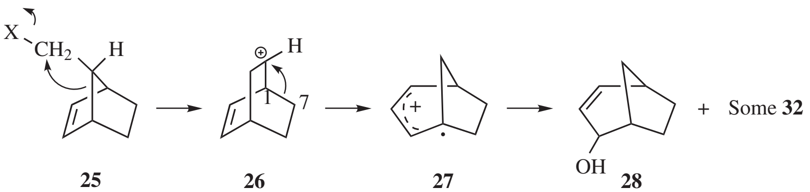
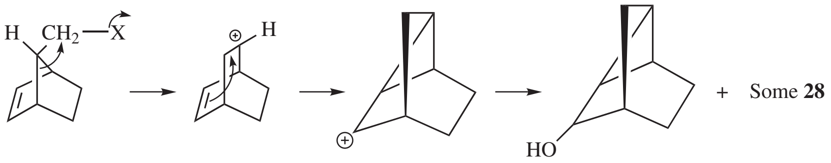
[39]Berson, J.A.; Poonian, M.S.; Libbey, W.J. *J. Am. Chem. Soc.* ***1969***, *91*, 5567; Berson, J.A.; Donald, D.S.; Libbey, W.J. *J. Am. Chem. Soc.* ***1969***, *91*, 5580; Berson, J.A.; Wege, D.; Clarke, G.M.; Bergman, R.G. *J. Am. Chem. Soc.* ***1969***, *91*, 5594, 5601.

the carbocation initially formed (**26** or **30**) seems to be the same for each. In the case of **26**, a second rearrangement (a shift of the 1,7 bond) follows, while with **30** what follows is an intramolecular addition of the positive carbon to the double bond.

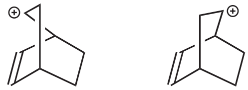


25 **26** **27** **28**



29 **30** **31** **32**

It seems as if **26** and **30** "remember" how they were formed before they go on to give the second step. Such effects are called *memory effects* and other such cases are known.[40] The causes of these effects are not well understood, though there has been much discussion. One possible cause is differential solvation of the apparently identical ions **26** and **30**. Other possibilities are (*1*) that the ions have geometrical structures that are twisted in opposite senses (e.g., a twisted **30** might have its positive carbon closer to the double



Twisted **30** Twisted **26**

bond than a twisted **26**); (*2*) that ion pairing is responsible;[41] and (*3*) that nonclassical carbocations are involved.[42] One possibility that has been ruled out is that the steps **25** → **26** → **27** and **29** → **30** → **31** are concerted, so that **26** and **30** never exist at all. This possibility has been excluded by several kinds of evidence, including the fact that **25** gives not only **28**, but also some **32**; and **29** gives some **28**

[40]For examples of memory effects in other systems, see Berson, J.A.; Luibrand, R.T.; Kundu, N.G.; Morris, D.G. *J. Am. Chem. Soc.* ***1971***, *93*, 3075; Collins, C.J. *Acc. Chem. Res.* ***1971***, *4*, 315; Collins, J.A.; Glover, I.T.; Eckart, M.D.; Raaen, V.F.; Benjamin, B.M.; Benjaminov, B.S. *J. Am. Chem. Soc.* ***1972***, *94*, 899; Svensson, T. *Chem. Scr.,* ***1974***, *6*, 22.

[41]See Collins, C.J. *Chem. Soc. Rev.* ***1975***, *4*, 251.

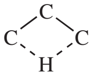
[42]See, for example, Seybold, G.; Vogel, P.; Saunders, M.; Wiberg, K.B. *J. Am. Chem. Soc.* ***1973***, *95*, 2045; Kirmse, W.; Günther, B. *J. Am. Chem. Soc.* ***1978***, *100*, 3619.

along with **32**. This means that some of the **26** and **30** ions interconvert, a phenomenon known as *leakage*.

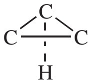
Longer Nucleophilic Rearrangements

The question as to whether a group can migrate with its electron pair from A to C in W–A–B–C or over longer distances has been much debated. Although claims have been made that alkyl groups can migrate in this way, the evidence is that such migration is extremely rare, if it occurs at all. One experiment that demonstrated this was the generation of the 3,3-dimethyl-1-butyl cation $Me_3CCH_2CH_2^+$. If 1,3-methyl migrations are possible, this cation would appear to be a favorable substrate, since such a migration would convert a primary cation into the tertiary 2-methyl-2-pentyl cation $Me_2CCH_2CH_2CH_3$, while the only possible 1,2 migration (of hydride) would give only a secondary cation. However, no products arising from the 2-methyl-2-pentyl cation were found, the only rearranged products being those formed by the 1,2 hydride migration.[43] 1,3 Migration of bromine has been reported.[44]

However, most of the debate over the possibility of 1,3 migrations has concerned not methyl or bromine, but 1,3 hydride shifts.[45] There is no doubt that *apparent* 1,3 hydride shifts take place (many instances have been found), but the question is whether they are truly direct hydride shifts or whether they occur by another



A



B

mechanism. There are at least two ways in which indirect 1,3-hydride shifts can take place: (*1*) by successive 1,2-shifts or (*2*) through the intervention of protonated cyclopropanes (see p. 1565). A direct 1,3-shift would have the transition state **A**, while the transition state for a 1,3-shift involving a protonated cyclopropane intermediate would resemble **B**. The evidence is that most reported 1,3 hydride shifts are actually the result of successive 1,2 migrations,[46] but that in some cases small amounts of products cannot be accounted for in this way. For example, the reaction of 2-methyl-1-butanol with KOH and bromoform gave a mixture of alkenes, nearly all of which could have arisen from simple

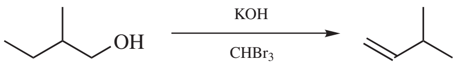
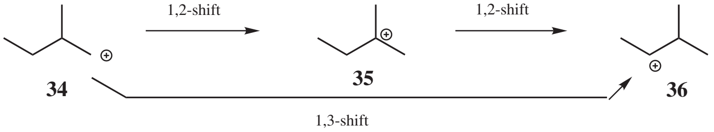
[46]For example, see Bundel', Yu.G.; Levina, I.Yu.; Krzhizhevskii, A.M.; Reutov, O.A. *Doklad. Chem.* ***1968***, *181*, 583; Fărcaşiu, D.; Kascheres, C.; Schwartz, L.H. *J. Am. Chem. Soc.* ***1972***, *94*, 180; Kirmse, W.; Knist, J.; Ratajczak, H. *Chem. Ber.* ***1976***, *109*, 2296.

elimination or 1,2-shifts of hydride or alkyl. However, 1.2% of the product was **33**:[47]



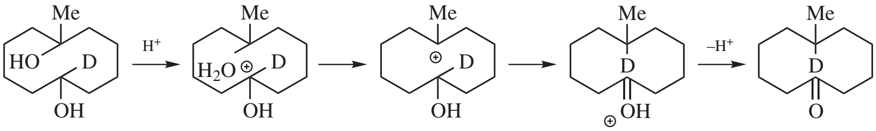
33

Hypothetically, **33** could have arisen from a 1,3-shift (direct or through a protonated cyclopropane) or from two successive 1,2-shifts:



34 **35** **36**

However, the same reaction applied to 2-methyl-2-butanol gave no **33**, which demonstrated that **36** was not formed from **35**. The conclusion made was that **36** was formed directly from **34**. This experiment does not answer the question as to whether **36** was formed by a direct shift or through a protonated cyclopropane, but from other evidence[48] it appears that 1,3 hydride shifts that do not result from successive 1,2 migrations usually take place through protonated cyclopropane intermediates (which, as we saw on p. 1565, account for only a small percentage of the product in any case). However, there is evidence that direct 1,3 hydride shifts by way of **A** may take place in super acid solutions.[49] Although direct nucleophilic rearrangements over distances >1,2 are rare (or perhaps nonexistent) when the migrating atom or group must move along a chain, this is not so for a shift across a ring of 8–11 members. Many such transannular rearrangements are known.[50] Several examples are given on p. 223. This is the mechanism of one of these:[51]



[47]Skell, P.S.; Maxwell, R.J. *J. Am. Chem. Soc.* ***1962***, *84*, 3963. See also, Skell, P.S.; Starer, I. *J. Am. Chem. Soc.* ***1962***, *84*, 3962.

[48]For example, see Brouwer, D.M.; van Doorn, J.A. *Recl. Trav. Chim. Pays-Bas* ***1969***, *8*, 573; Dupuy, W.E.; Goldsmith, E.A.; Hudson, H.R. *J. Chem. Soc. [50]For reviews, see Cope, A.C.; Martin, M.M.; McKervey, M.A. *Q. Rev. Chem. Soc.* ***1966***, *20*, 119. For many references, see Blomquist, A.T.; Buck, C.J. *J. Am. Chem. Soc.* ***1951***, *81*, 672.

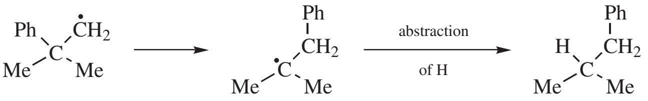
[51]Prelog, V.; Küng, W. *Helv. Chim. Acta* ***1956***, *39*, 1394.

It is noteworthy that the *methyl* group does not migrate in this system. It is generally true that alkyl groups do not undergo transannular migration.[52] In most cases, it is hydride that undergoes this type of migration, though a small amount of phenyl migration has also been shown.[53]

Free-Radical Rearrangements[54]

1,2-Free-radical rearrangements are much less common than the nucleophilic type previously considered, for the reasons mentioned on p. 1559. Where they do occur, the general pattern is similar. There must first be generation of a free radical, and then the actual migration in which the migrating group moves with one electron:

Finally, the new free radical must stabilize itself by a further reaction. The order of radical stability leads us to predict that here too, as with carbocation rearrangements, any migrations should be in the order primary → secondary → tertiary, and that the logical place to look for them should be in neopentyl and neophyl systems. The most common way of generating free radicals for the purpose of detection of rearrangements is by decarbonylation of aldehydes (**14-32**). In this manner, it was found that neophyl radicals *do* undergo rearrangement. Thus, $PhCMe_2CH_2CHO$ treated with di-*tert*-butyl peroxide gave about equal amounts of the normal product $PhCMe_2CH_3$ and the product arising from migration of phenyl:[55]



[52]For an apparent exception, see Fărcaşiu, D.; Seppo, E.; Kizirian, M.; Ledlie, D.B.; Sevin, A. *J. Am. Chem. Soc.* ***1989***, *111*, 8466.

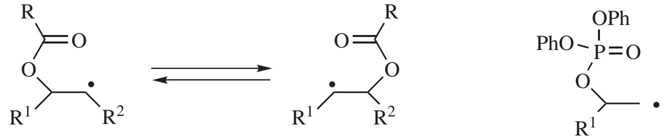
Many other cases of free-radical migration of aryl groups have been found.[56] Intramolecular radical rearrangements are known.[57] The C-4 radicals of α- and β-thujone undergo two distinct rearrangement reactions, and it has been proposed that these could serve as simultaneous, but independent radical clocks.[58]

A 1,2-shift has been observed in radicals bearing an OCOR group at the β-carbon where the oxygen group migrates as shown in the interconversion of **37** and **38**. This has been proven by ^{18}O isotopic labeling experiments[59] and other mechanistic explorations.[60] A similar rearrangement was observed with phosphatoxy alkyl radicals, such as **39**.[61] A 1,2-shift of hydrogen atoms has been observed in aryl radicals.[62]



37 **38** **39**

A C → N 1,2-aryl rearrangement was observed when alkyl azides were treated with *n*-Bu_3SnH, proceeding via an C–N•–$SnBu_3$ species to give an imine.[63]

It is noteworthy that the extent of migration is much less than with corresponding carbocations: Thus in the example given, there was only ~50% migration, whereas the carbocation would have given much more. Also noteworthy is that there was no migration of the methyl group. In general, it may be said that free-radical migration of alkyl groups does not occur at ordinary temperatures. Many attempts have been made to detect such migration on the traditional neopentyl and bornyl types of substrates. However, alkyl migration is not observed, even in substrates where the corresponding carbocations undergo facile rearrangement.[64] Another type of migration that is very common for carbocations, but not observed

[56]For example, see Curtin, D.Y.; Hurwitz, M.J. *J. Am. Chem. Soc.* ***1952***, *74*, 5381; Wilt, J.K.; Philip, H. *J. Org. for free radicals, is 1,2 migration of hydrogen. We confine ourselves to a few examples of the lack of migration of alkyl groups and hydrogen:

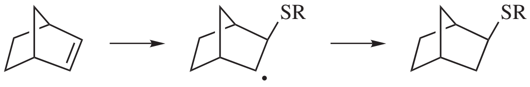
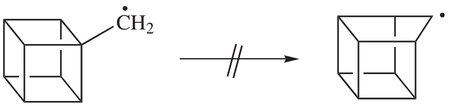
1. 3,3-Dimethylpentanal ($EtCMe_2CH_2CHO$) gave no rearranged products on decarbonylation.[65]

2. Addition of RSH to norbornene gave only *exo*-norbornyl sulfides, though **40** is an intermediate, and the corresponding carbocation cannot be formed without rearrangement.[66]



40

3. The cubylcarbinyl radical did not rearrange to the 1-homocubyl radical, though doing so would result in a considerable decrease in strain.[67]



Cubylcarbinyl radical   1-Homocubyl radical

4. It was shown[68] that no rearrangement of isobutyl radical to *tert*-butyl radical (which would involve the formation of a more stable radical by a hydrogen shift) took place during the chlorination of isobutane.

However, 1,2 migration of alkyl groups has been shown to occur in certain *diradicals*.[69] For example, the following rearrangement has been established by tritium labeling.[70]

In this case, the fact that migration of the methyl group leads directly to a compound in which all electrons are paired undoubtedly contributes to the driving force of the reaction.

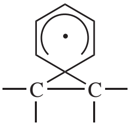
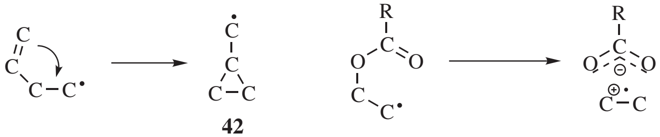
The fact that aryl groups migrate, but alkyl groups and hydrogen generally do not, leads to the proposition that **41**, in which the odd electron is not found in the three-membered ring, may be an intermediate. There has been much controversy on this point, but the bulk of the evidence indicates that **41** is a transition state, not an intermediate.[71] Among the evidence is the failure to observe **41** either by ESR[72] or CIDNP.[73] Both of these techniques can detect free radicals with extremely short lifetimes (pp. 266–268).[74]



41

Besides aryl, vinylic[75] and acetoxy groups[76] also migrate. Vinylic groups migrate by way of a cyclopropylcarbinyl radical intermediate (**42**),[77] while the migration of acetoxy groups may involve the charge-separated structure shown.[78] Thermal isomerization of 1-(3-butenyl)cyclopropane at 415°C leads to bicyclo[2.2.1]heptane.[79] Migration has been observed for chloro (and to a much lesser extent



bromo) groups. For example, in the reaction of $Cl_3CCH{=}CH_2$ with bromine under the influence of peroxides, the products were 47% $Cl_3CCHBrCH_2Br$

[71]For molecular-orbital calcualtions indicating that **41** is an intermediate, see Yamabe, S. *Chem. Lett.* ***1989***, 1523.

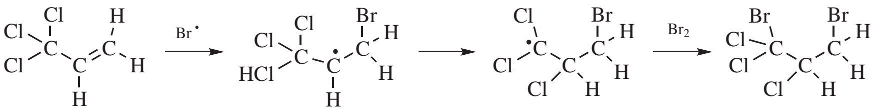
(the normal addition product) and 53% $BrCCl_2CHClCH_2Br$, which arose by rearrangement:

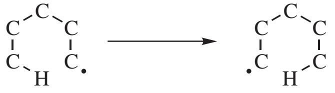


In this particular case, the driving force for the rearrangement is the particular stability of dichloroalkyl free radicals. Nesmeyanov, Freidlina, and co-workers have extensively studied reactions of this sort.[80] It has been shown that the 1,2 migration of Cl readily occurs if the migration origin is tertiary and the migration terminus primary.[81] Migration of Cl and Br could take place by a transition state in which the odd electron is accommodated in a vacant *d* orbital of the halogen.

Migratory aptitudes have been measured for the phenyl and vinyl groups, and for three other groups, using the system $RCMe_2CH_2\bullet \rightarrow Me_2\dot{C}\,CH_2R$. These were found to be in the order R = $H_2C{=}CH_2 > Me_3CC{=}O > Ph > Me_3C{\equiv}C > CN$.[82]

In summary then, 1,2 free-radical migrations are much less prevalent than the analogous carbocation processes, and are important only for aryl, vinylic, acetoxy, and halogen migrating groups. The direction of migration is normally toward the more stable radical, but "wrong-way" rearrangements are also known.[83]

Despite the fact that hydrogen atoms do not migrate 1,2, longer free-radical migrations of hydrogen are known.[84] The most common are 1,5-shifts, but 1,6 and longer shifts have also been found. The possibility of 1,3 hydrogen shifts has been much investigated, but it is not certain if any actually occur. If they do they are rare, presumably because the most favorable geometry for C•••H•••C in the transition state is linear and this geometry cannot be achieved in a 1,3-shift. 1,4-Shifts are definitely known, but are still not very common. These long shifts are best regarded as internal abstractions of hydrogen (for reactions involving them, see **14-6** and **18-40**):



Transannular shifts of hydrogen atoms have also been observed.[85]

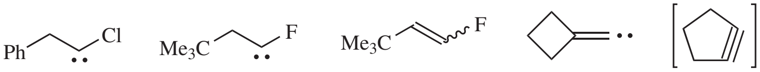
Carbene Rearrangements[86]

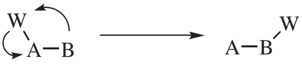
Carbenes can rearrange to alkenes in many cases.[87] A 1,2-hydrogen shift leads to an alkene, and this is often competitive with insertion reactions.[88] Benzylchlorocarbene (**43**) rearranges via a 1,2 hydrogen shift to give the alkene.[89] Similarly, carbene **44** rearranges to alkene **45**, and replacement of H on the α-carbon with D showed a deuterium isotope effect of ~5.[90] Vinylidene carbene ($H_2C{=}C{:}$) rearranges to acetylene.[91] Rearrangement of alkylidene carbene **46** has been calculated to give the highly unstable cyclopentyne (**47**), which cannot be isolated, but can give a [2 + 2]-cycloaddition product when generated in the presence of a simple alkene.[92] The spiro carbenes undergo rearrangement reactions.[93]



43 **44** **45** **46** **47**

Electrophilic Rearrangements[94]

Rearrangements in which a group migrates without its electrons are much rarer than the two kinds previously considered, but the general principles are the same. A carbanion (or other negative ion) is created first, and the actual rearrangement step involves migration of a group without its electrons:



The product of the rearrangement may be stable or may react further, depending on its nature (see also, pp. 1585). An *ab initio* study predicts that a [1,2]-alkyl shift in alkyne anions should be facile.[95]

REACTIONS

The reactions in this chapter are classified into three main groups and 1,2-shifts are considered first. Within this group, reactions are classified according to (*1*) the identity of the substrate atoms A and B and (*2*) the nature of the migrating group W. In the second group are the cyclic rearrangements. The third group consists of rearrangements that cannot be fitted into either of the first two categories.

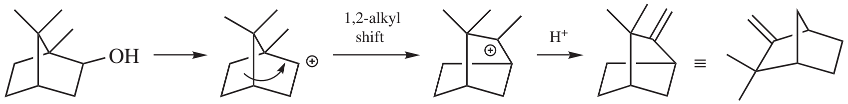
Reactions in which the migration terminus is on an aromatic ring have been treated under aromatic substitution. These are **11-27–11-32**, **11-36**, **13-30–13-32**, and, partially, **11-33**, **11-38**, and **11-39**. Double-bond shifts have also been treated in other chapters, though they may be considered rearrangements (p. $$$, p. $$$, and **12-2**). Other reactions that may be regarded as rearrangements are the Pummerer (**19-83**) and Willgerodt (**19-84**) reactions.

1,2-REARRANGEMENTS

A. Carbon-to-Carbon Migrations of R, H, and Ar

18-1 Wagner–Meerwein and Related Reactions

1/Hydro,1/hydroxy-(2/ → 1/alkyl)-*migro*-elimination, and so on



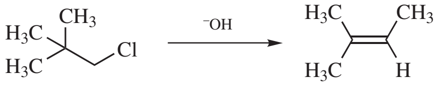
isoborneol **48** **49** camphene

Wagner–Meerwein rearrangements were first discovered in the bicyclic terpenes, and most of the early development of this reaction was with these compounds.[96] An example is the conversion of isoborneol to camphene. It fundamentally involves a 1,2 alkyl shift of an intermediate carbocation, such as **48** → **49**. When alcohols are treated with acids, simple substitution (e.g., **10-48**) or elimination (**17-1**) usually accounts for most or all of the products. But in many cases, especially where two or three alkyl or aryl groups are on the β carbon, some or all of the product is rearranged. These rearrangements have been called *Wagner–Meerwein rearrangements*, although this term is nowadays reserved for relatively specific transformations, such as isoborneol to camphene and related reactions. As pointed out previously, the carbocation that is a direct product of the rearrangement must stabilize itself, and most often it does this by the loss

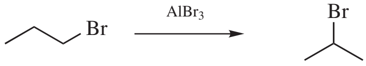
[96]For a review of rearrangements in bicyclic systems, see Hogeveen, H.; van Kruchten, E.M.G.A. *Top. Curr. Chem.* ***1979***, *80*, 89. For reviews concerning caranes and pinanes see, respectively, Arbuzov, B.A.; Isaeva, Z.G. *Russ. Chem. Rev.* ***1976***, *45*, 673; Banthorpe, D.V.; Whittaker, D. *Q. Rev. Chem. Soc.* ***1966***, *20*, 373.

of a hydrogen β to it, so the rearrangement product is usually an alkene.[97] If there is a choice of protons, Zaitsev's rule (p. 1482) governs the direction, as we might expect. Sometimes a different positive group is lost instead of a proton. Less often, the new carbocation stabilizes itself by combining with a nucleophile instead of losing a proton. The nucleophile may be the water that is the original leaving group, so that the product is a rearranged alcohol, or it may be some other species present (solvent, added nucleophile, etc.). Rearrangement is usually predominant in neopentyl and neophyl types of substrates, and with these types normal nucleophilic substitution is difficult (normal elimination is of course impossible). Under S_N2 conditions, substitution is extremely slow;[98] and under S_N1 conditions, carbocations are formed that rapidly rearrange. However, free-radical substitution, unaccompanied by rearrangement, can be carried out on neopentyl systems, though, as we have seen (p. 1574), neophyl systems undergo rearrangement as well as substitution.

Example *a*

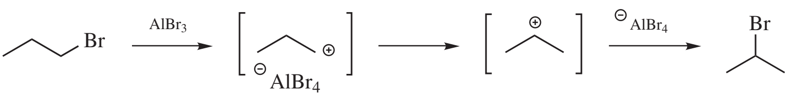


Example *b*



Examples of Wagner–Meerwein-type rearrangements are found in simpler systems, such as neopentyl chloride (example *a*) and even 1-bromopropane (example *b*). These two examples illustrate the following points:

1. Hydride ion can migrate. In example *b*, it was hydride that shifted, not bromine:



2. The leaving group does not have to be H_2O, but can be any departing species whose loss creates a carbocation, including N_2 from aliphatic diazonium ions[99] (see the section on leaving groups in nucleophilic substitution, p. 438). Also, rearrangement may follow when the carbocation is created by addition of a proton or other positive species to a double bond. Even alkanes give

[97]For a review of such rearrangements, see Kaupp, G. *Top. Curr. Chem.* ***1988***, *146*, 57.

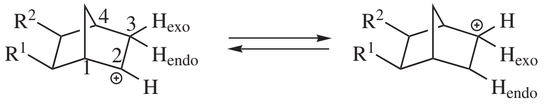
rearrangements when heated with Lewis acids, provided some species is initially present to form a carbocation from the alkane.

3. Example *b* illustrates that the last step can be substitution instead of elimination.
4. Example *a* illustrates that the new double bond is formed in accord with Zaitsev's rule.

2-Norbornyl cations (see **48**), besides displaying the 1,2-shifts of a CH_2 group previously illustrated for the isoborneol → camphene conversion, are also prone to rapid hydride shifts from the 3 to the 2 position (known as 3,2-shifts). These 3,2-shifts usually take place from the exo side;[100] that is, the 3-exo hydrogen migrates to the 2-exo position.[101] This stereoselectivity is analogous to the behavior we have previously seen for norbornyl



systems, namely, that nucleophiles attack norbornyl cations from the exo side (p. 461) and that addition to norbornenes is also usually from the exo direction (p. 1023).

For rearrangements of alkyl carbocations, the direction of rearrangement is usually toward the most stable carbocation (or radical), which is tertiary > secondary > primary, but rearrangements in the other direction have also been found,[102] and often the product is a mixture corresponding to an equilibrium mixture of the possible carbocations. In the Wagner–Meerwein rearrangement, the rearrangement has been observed for a secondary to a secondary carbocation rearrangement, leading to some controversy. Winstein[103] described norbornyl cations in terms of the resonance structures represented by the nonclassical ion **50**.[104] This view was questioned, primarily by Brown,[105] who suggested that the facile rearrangements could be explained by a series of fast 1,3-Wagner–Meerwein shifts.[106]

[100]For example, see Kleinfelter, D.C.; Schleyer, P.v.R. *J. Am. Chem. Soc.* ***1961***, *83*, 2329; Collins, C.J.; Cheema, Z.K.; Werth, R.G.; Benjamin, B.M. *J. Am. Chem. Soc.* ***1970***, *92*, 1990. See also, Story, R.R.; Clark, B.C., in Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, Vol. 3, Wiley, New York, ***1972***, p. 1007.

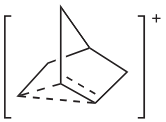
[106]Brown, H.C.; Ravindranathan, M. *J. Am. Chem. Soc.* ***1978***, *100*, 1865.

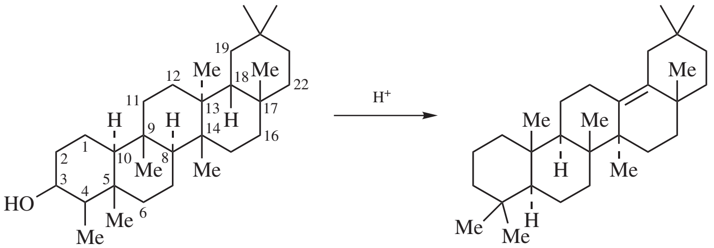
There is considerable evidence, however, that the norbornyl cation rearranges with σ-participation,[107] and there is strong NMR evidence for the nonclassical ion in super acids at low temperatures.[108]



50

As alluded to above, the term "Wagner–Meerwein rearrangement" is not precise. Some use it to refer to all the rearrangements in this section and in **18-2**. Others use it only when an alcohol is converted to a rearranged alkene. Terpene chemists call the migration of a methyl group the *Nametkin rearrangement.* The term *retropinacol rearrangement* is often applied to some or all of these. Fortunately, this disparity in nomenclature does not seem to cause much confusion.

Sometimes several of these rearrangements occur in one molecule, either simultaneously or in rapid succession. A spectacular example is found in the triterpene series. Friedelin is a triterpenoid ketone found in cork. Reduction gives 3β-friedelanol (**51**). When this compound is treated with acid, 13(18)-oleanene (**52**) is formed.[109] In this case, *seven* 1,2-shifts take place. On removal of H_2O from position 3 to leave a positive



51 **52**

charge, the following shifts occur: hydride from 4 to 3; methyl from 5 to 4; hydride from 10 to 5; methyl from 9 to 10; hydride from 8 to 9; methyl from 14 to 8; and methyl from 13 to 14. This leaves a positive charge at position 13, which is stabilized by loss of the proton at the 18 position to give **52**. All these shifts are stereospecific, the group always migrating on the side of the ring system on which it is located; that is, a group above the "plane" of the ring system (indicated by a solid line in **51**) moves above the plane, and a group below the plane (dashed line) moves

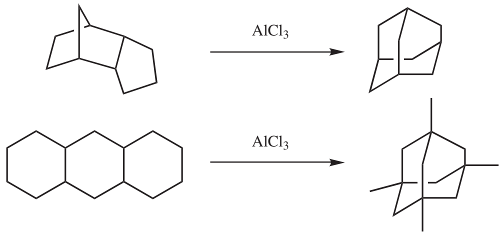
below it. It is probable that the seven shifts are not all concerted, although some of them may be, for intermediate products can be isolated.[110] As an illustration of point 2 (p. 1581), it may be mentioned that friedelene, derived from dehydration of **51**, also gives **52** on treatment with acid.[111]

It was mentioned above that even alkanes undergo Wagner–Meerwein rearrangements if treated with Lewis acids and a small amount of initiator. Catalytic asymmetric Wagner–Meerwein shifts have been observed.[112] An interesting application of this reaction is the conversion of tricyclic molecules to adamantane and its derivatives.[113] It has been found that *all* tricyclic alkanes containing 10 carbons are converted to adamantane by treatment with a Lewis acid, such as $AlCl_3$. If the substrate contains >10 carbons, alkyl-substituted adamantanes are produced. The IUPAC name for these reactions is *Schleyer adamantization*. Two examples are



If 14 or more carbons are present, the product may be diamantane or a substituted diamantane.[114] These reactions are successful because of the high thermodynamic stability of adamantane, diamantane, and similar diamond-like molecules. The most stable of a set of C_nH_m isomers (called the *stabilomer*) will be the end product if the reaction reaches equilibrium.[115] Best yields are obtained by the use of "sludge" catalysts[116] (i.e., a mixture of AlX_3 and *tert*-butyl bromide or *sec*-butyl bromide).[117] Though it is certain that these adamantane-forming reactions take place by nucleophilic 1,2-shifts, the exact pathways are not easy to unravel

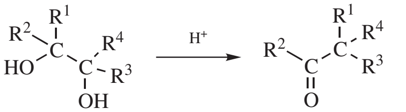
because of their complexity.[118] Treatment of adamantane-2-^{14}C with $AlCl_3$ results in total carbon scrambling on a statistical basis.[119]

As already indicated, the mechanism of the Wagner–Meerwein rearrangement is usually nucleophilic. Free-radical rearrangements are also known (see the mechanism section of this chapter), though virtually only with aryl migration. However, carbanion mechanisms (electrophilic) have also been found.[94] Thus Ph_3CCH_2Cl treated with sodium gave Ph_2CHCH_2Ph along with unrearranged products.[120] This is called the *Grovenstein–Zimmerman rearrangement*. The intermediate is Ph_3CCH_2-, and the phenyl moves without its electron pair. Only aryl and vinylic,[121] and not alkyl, groups migrate by the electrophilic mechanism (p. $$$) and transition states or intermediates analogous to **41** and **42** are likely.[122]

OS **V**, 16, 194; **VI**, 378, 845.

18-2 The Pinacol Rearrangement

1/*O*-Hydro,3/hydroxy-(2/ → 3/alkyl)-*migro*-elimination



R = alkyl, aryl, or hydrogen

When *vic*-diols (glycols) are treated with acids,[123] they can be rearranged to give aldehydes or ketones, although elimination without rearrangement can also be accomplished. This reaction is called the *pinacol rearrangement*; the reaction gets its name from a prototype compound pinacol ($Me_2COHCOHMe_2$), which is rearranged to pinacolone (Me_3CCOCH_3).[124] In this type of reaction, reduction can compete with rearrangement.[125] The reaction has been accomplished many times, with alkyl, aryl, hydrogen, and even ethoxycarbonyl (COOEt)[126] as migrating

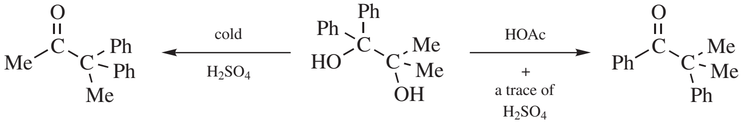
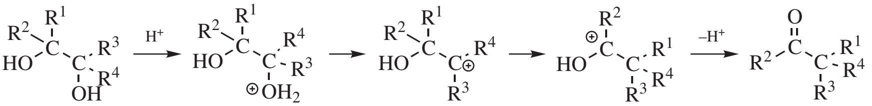
groups. In most cases, each carbon has at least one alkyl or aryl group, and the reaction is most often carried out with tri- and tetrasubstituted glycols. As mentioned earlier, glycols in which the four R groups are not identical can give rise to more than one product, depending on which group migrates (see p. 1568 for a discussion of migratory aptitudes). A noncatalytic reaction is possible in supercritical water.[127]

Stereodifferentiation is possible in this reaction.[128] When TMSOTf was used to initiate the reaction, it was shown to be highly regioselective.[129] Mixtures are often produced, and which group preferentially migrates may depend on the reaction conditions, as well as on the nature of the substrate. Thus the



54 53 55

action of cold, concentrated sulfuric acid on **53** produces mainly the ketone **54** (methyl migration), while treatment of **53** with acetic acid containing a trace of sulfuric acid gives mostly **55** (phenyl migration).[130] If at least one R is hydrogen, aldehydes can be produced as well as ketones. Generally, aldehyde formation is favored by the use of mild conditions (lower temperatures, weaker acids), because under more drastic conditions the aldehydes may be converted to ketones (**18-4**). The reaction has been carried out in the solid state, by treating solid substrates with HCl gas or with an organic solid acid.[131]



56

The mechanism involves a simple 1,2-shift. The ion **56** (where all four R groups are Me) has been trapped by the addition of tetrahydrothiophene.[132] It may seem odd that a migration takes place when the positive charge is already at a tertiary position, but carbocations stabilized by an oxygen atom are even more stable than tertiary alkyl cations (p. 242). There is also the driving force supplied by the fact that the new carbocation can immediately stabilize itself by losing a proton.

It is obvious that other compounds in which a positive charge can be placed on a carbon α to one bearing an OH group can also give this rearrangement. This is true for β-amino alcohols, which rearrange on treatment with nitrous acid (this is called

A good way to prepare β-diketones consists of heating α,β-epoxy ketones at 80–140°C in toluene with small amounts of $(Ph_3P)_4Pd$ and 1,2-bis(diphenylphosphino)ethane.[150] Epoxides are converted to 1,2-diketones with Bi, DMSO, O_2, and a catalytic amounts of $Cu(OTf)_2$ at 100°C.[151] α,β–Epoxy ketones are also converted to 1,2-diketones with a ruthenium catalyst[152] or an iron catalyst.[153] Epoxides with an α-hydroxyalkyl substituent give a pinacol rearrangement product in the presence of a $ZnBr_2$[154] or $Tb(OTf)_3$[155] catalyst to give a γ-hydroxy ketone.

Oxaziridines are converted to ring-expanded lactams under photochemical conditions.[156] *N*-Tosyl aziridines with an α-hydroxyalkyl substituent give a pinacol rearrangement product in the presence of Lewis acids, such as SmI_2, in this case a keto-*N*-tosyl amide.[157]

β-Hydroxy ketones can be prepared by treating the silyl ethers (**57**) of α,β-epoxy alcohols with $TiCl_4$.[158]

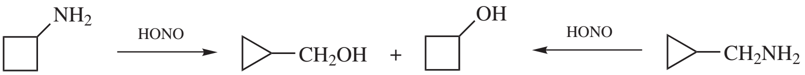
18-3 Expansion and Contraction of Rings

Demyanov ring contraction; Demyanov ring expansion



When a positive charge is formed on an alicyclic carbon, migration of an alkyl group can take place to give ring contraction, producing a ring that is one carbon smaller than the original, as in the interconversion of the cyclobutyl cation and the

cyclopropylcarbinyl cation.

Note that this change involves conversion of a secondary to a primary carbocation. In a similar manner, when a positive charge is placed on a carbon a to an alicyclic ring, ring expansion can take place.[159] The new carbocation, and the old one, can then give products by combination with a nucleophile (e.g., the alcohols shown above), or by elimination, so that this reaction is a special case of **18-1**. Often, both rearranged and unrearranged products are formed, so that, for example, cyclobutylamine and cyclopropylmethylamine give similar mixtures of the two alcohols shown above on treatment with nitrous acid (a small amount of 3-buten-1-ol is also produced). When the carbocation is formed by diazotization of an amine, the reaction is called the *Demyanov rearrangement*,[160] but of course similar products are formed when the carbocation is generated in other ways. The expansion reaction has been performed on rings of C_3–C_8,[161] but yields are best with the smaller rings, where relief of small-angle strain provides a driving force for the reaction. The contraction reaction has been applied to four-membered rings and to rings of C_6–C_8, but contraction of a cyclopentyl cation to a cyclobutylmethyl system is generally not feasible because of the additional strain involved. Strain is apparently much less of a factor in the cyclobutyl–cyclopropylmethyl interconversion (for a discussion of this interconversion, see p. 450). The influence of substituents on this rearrangement has been examined.[162]

Ring expansions of certain hydroxyamines, such as **58**

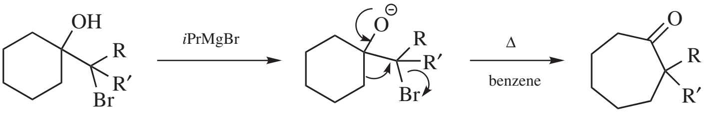
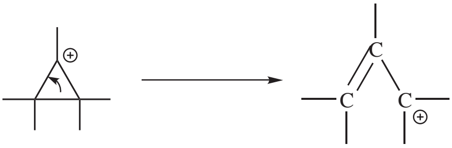
are analogous to the semipinacol rearrangement (**18-2**). This reaction is called the *Tiffeneau–Demyanov ring expansion*. These have been performed on rings of C_4–C_8 and the yields are better than for the simple Demyanov ring expansion. A similar reaction has been used to expand rings of from five to eight members.[163] In this case, a cyclic bromohydrin of the form **59** is treated with a Grignard reagent which, acting as a base, removes the OH proton to give the alkoxide **60**. Refluxing of **60** brings about the ring enlargement. The reaction has been accomplished for **59** in which at least one R group is phenyl or methyl,[164] but fails when both R groups are hydrogen.[165]

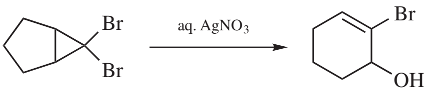


59 **60**

A positive charge generated on a three-membered ring gives "contraction" to an allylic cation.[166]



We have previously seen (p. 487) that this is the reason nucleophilic substitutions are not feasible at a cyclopropyl substrate. The reaction is often used to convert cyclopropyl halides and tosylates to allylic products, especially for the purpose of ring expansion, an example being the conversion of **61–62**.[167] The stereochemistry of these cyclopropyl cleavages is governed by the principle of orbital symmetry conservation (for a discussion, see p. 1644).



61 **62**

Three-membered rings can also be cleaved to unsaturated products in at least two other ways. (*1*) On pyrolysis, cyclopropanes can undergo "contraction" to

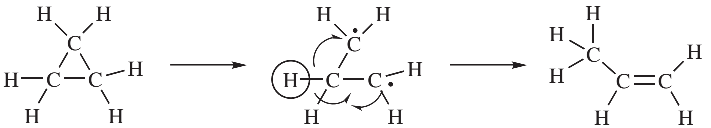
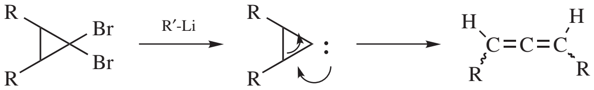
[167]Skell, P.S.; Sandler, S.R. *J. Am. Chem. Soc.* ***1958***, *80*, 2024.

propenes.[168] In the simplest case, cyclopropane gives propene when heated to 400–500°C. The mechanism is generally regarded[169] as involving a diradical

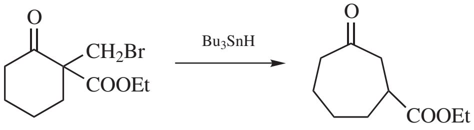


intermediate[170] (recall that free-radical 1,2 migration is possible for diradicals, p. 1574). (*2*) The generation of a carbene or carbenoid carbon in a three-membered ring can lead to allenes, and allenes are often prepared in this



way.[171] Flash vacuum pyrolysis of 1-chlorocyclopropene thermally rearranges to chloroallene.[172] One way to generate, such a species is treatment of a 1,1-dihalocyclopropane with an alkyllithium compound (**12-39**).[173] In contrast, the generation of a carbene or carbenoid at a cyclopropylmethyl carbon gives ring expansion.[174]

Some free-radical ring enlargements are also known, an example being:[175]



[168]For reviews, see Berson, J.A., in de Mayo, P. *Rearrangaements in Ground and Excited States*, Vol. 1, Academic Press, NY, ***1980***, pp. 324–352; *Ann. Rev. Phys. Chem.* ***1977***, *28*, 111; Bergman, R.G., in Kochi, J.K. *Free Radicals*, Vol. 1, Wiley, NY, ***1973***, pp. 191–237; Frey, H.M. *Adv. Phys. Org. Chem.* ***1966***, *4*, 147, see pp. 148–170.

[169]For evidence that diradical intermediates may not be involved, at least in some cases, see Fields, R.; Haszeldine, R.N.; Peter, D. *Chem. Commun.* ***1967***, 1081; Parry, K.A.W.; Robinson, P.J. *Chem. Commun.* ***1967***, 1083; Clifford, R.P.; Holbrook, K.A. *J. Chem. Soc. Perkin Trans. 2* ***1972***, 1972; Baldwin, J.E.; Grayston, M.W. *J. Am. Chem. Soc.* ***1974***, *96*, 1629, 1630.

[170]We have seen before that such diradicals can close up to give cyclopropanes (**17-34**). Therefore, pyrolysis of cyclopropanes can produce not only propenes, but also isomerized (cis → trans or optically active → inactive) cyclopropanes. See, for example, Berson, J.A.; Balquist, J.M. *J. Am. Chem. Soc.* ***1968***, *90*, 7343; Bergman, R.G.; Carter, W.L. *J. Am. Chem. Soc.* ***1969***, *91*, 7411.

[171]For reviews, see Schuster, H.F.; Coppola, G.M. *Allenes in Organic Synthesis*, Wiley, NY, ***1984***, pp. 20–23; Kirmse, W. *Carbene Chemistry*, 2nd ed., Academic Press, NY, ***1971***, pp. 462–467.

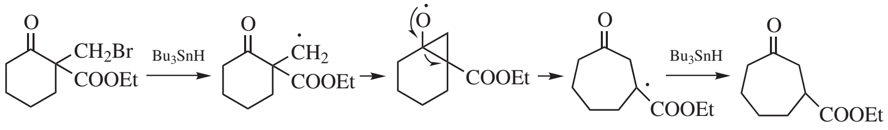
This reaction has been used to make rings of 6, 7, 8, and 13 members. A possible mechanism is



This reaction has been extended to the expansion of rings by three or four carbons, by the use of a substrate containing $(CH_2)_nX$ ($n = 3$ or 4) instead of CH_2Br.[176] By this means, 5-, 6-, and 7-membered rings were enlarged to 18–11-membered rings.

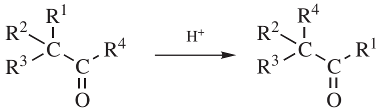
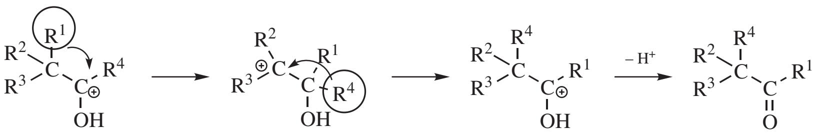
18-4 Acid-Catalyzed Rearrangements of Aldehydes and Ketones

1/Alkyl,2/alkyl-interchange, and so on

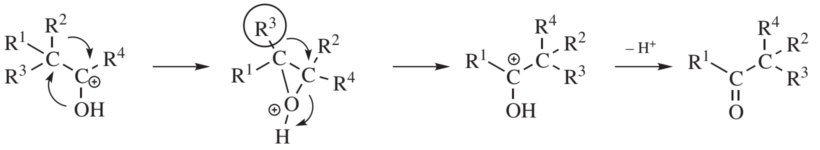


Rearrangements of this type, where a group α to a carbonyl "changes places" with a group attached to the carbonyl carbon, occur when migratory aptitudes are favorable.[177] The R^2, R^3, and R^4 groups may be alkyl or hydrogen. Certain aldehydes have been converted to ketones, and ketones to other ketones (though more drastic conditions are required for the latter), but no rearrangement of a ketone to an aldehyde ($R^1 = H$) has so far been reported. There are two mechanisms,[178] each beginning with protonation of the oxygen and each involving two migrations. In one pathway, the migrations are in opposite directions:[179]

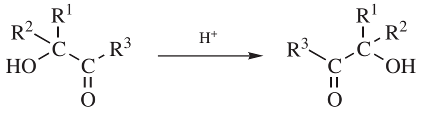


[176]Dowd, P.; Choi, S. *J. Am. Chem. Soc.* ***1987***, *109*, 6548; *Tetrahedron Lett.* ***1991***, *32*, 565.
[177]For reviews, see Fry, A. *Mech. Mol. Migr.* ***1971***, *4*, 113; Collins, C.J.; Eastham, J.F., in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, ***1966***, pp. 771–790.
[178]Favorskii, A.; Chilingaren, A. *C. R. Acad. Sci.* ***1926***, *182*, 221.
[179]Kendrick Jr., L.W.; Benjamin, B.M.; Collins, C.J. *J. Am. Chem. Soc.* ***1958***, *80*, 4057; Rothrock, T.S.; Fry, A. *J. Am. Chem. Soc.* ***1958***, *80*, 4349; Collins, C.J.; Bowman, N.S. *J. Am. Chem. Soc.* ***1959***, *81*, 3614.

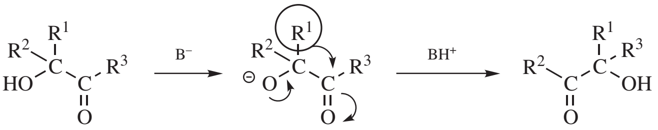
In the other pathway, the migrations are in the same direction. The actual mechanism of this pathway is not certain, but an epoxide (protonated) intermediate[180] is one possibility:[181]



If the reaction is carried out with ketone labeled in the C=O group with ^{14}C, the first pathway predicts that the product will contain all the ^{14}C in the C=O carbon, while in the second pathway the label will be in the α carbon (demonstrating migration of oxygen). The results of such experiments[182] have shown that in some cases only the C=O carbon was labeled, in other cases only the a carbon, while in still others both carbons bore the label, indicating that in these cases both pathways were in operation. With α-hydroxy aldehydes and ketones, the process may stop after only one migration (this is called the *α-ketol* rearrangement).

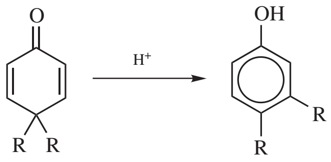


The α-ketol rearrangement can also be brought about by base catalysis, but only if the alcohol is tertiary, since if R^1 or R^2 = hydrogen, enolization of the substrate is more favored than rearrangement.



18-5 The Dienone–Phenol Rearrangement

2/*C* → 5/*O*-Hydro,1/*C* → 2/*C*-alkyl-bis-migration

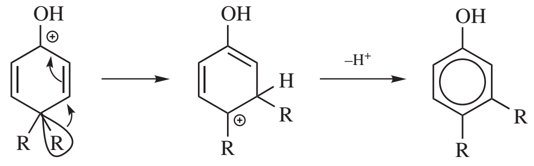


[180]Zook, H.D.; Smith, W.E.; Greene, J.L. *J. Am. Chem. Soc.* ***1957***, *79*, 4436.

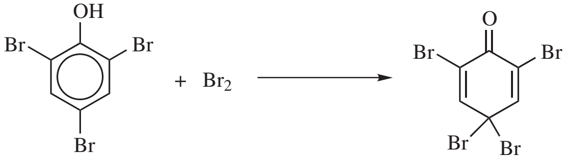
[181]Some such pathway is necessary to account for the migration of oxygen that is found. It may involve a protonated epoxide, a 1,2-diol, or simply a [1,2]-shift of an OH group.

[182]See, for example, Barton, S.; Porter, C.R. *J. Chem. Soc.* ***1956***, 2483; Zalesskaya, T.E.; Remizova, T.B. *J. Gen. Chem. USSR* ***1965***, *35*, 29; Fry, A.; Oka, M. *J. Am. Chem. Soc.* ***1979***, *101*, 6353.

Cyclohexadienone derivatives that have two alkyl groups in the 4 position undergo, on acid treatment,[183] 1,2 migration of one of these groups from **64** to give the phenol. Note that a photochemical version of this reaction has been observed.[184]

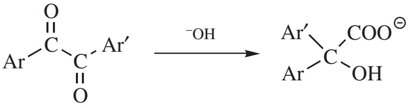


The driving force in the overall reaction (the *dienone–phenol rearrangement*) is of course creation of an aromatic system.[185] Note that **63** and **64** are arenium ions (p. 240), the same as those generated by attack of a phenol on an electrophile.[186] Sometimes, in the reaction of a phenol with an electrophile, a kind of reverse rearrangement (called the *phenol–dienone rearrangement)* takes place, though without an actual migration.[187] An example is



18-6 The Benzil–Benzilic Acid Rearrangement

1/*O*-Hydro,3/oxido-(1/ → 2/aryl)-*migro*-addition



When treated with base, α-diketones rearrange to give the salts of α-hydroxy acids, a reaction known as the *benzil-benzilic acid rearrangement* (benzil is

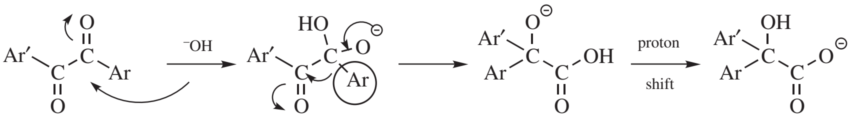
PhCOCOPh; benzilic acid is $Ph_2COHCOOH$).[188] A rhodium catalyzed version of this reaction has also been reported.[189] Though the reaction is usually illustrated with aryl groups, it can also be applied to aliphatic diketones[190] and to α-keto aldehydes. The use of an alkoxide instead of hydroxide gives the corresponding ester directly,[191] though alkoxide ions that are readily oxidized (e.g., OEt^- or $OCHMe_2^-$) are not useful here, since they reduce the benzil to a benzoin. The mechanism is similar to the rearrangements in **18-1–18-4**, but there is a difference: The migrating group does not move to a carbon with an open sextet. The carbon makes room for the migrating group by releasing a pair of π electrons from the C=O bond to the oxygen. The first step is attack of the base at the carbonyl group, the same as the first step of the tetrahedral mechanism of nucleophilic substitution (p. 1254) and of many additions to the C=O bond (Chapter 16):

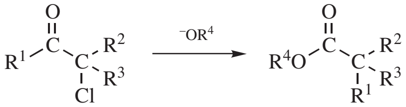


The mechanism has been intensely studied,[188] and there is much evidence for it.[192] The reaction is irreversible.

OS **I**, 89.

18-7 The Favorskii Rearrangement

2/Alkoxy-de-chloro(2/ → 1/alkyl)-*migro*-substitution



The reaction of α-halo ketones (chloro, bromo, or iodo) with alkoxide ions[193] to give rearranged esters is called the *Favorskii rearrangement*.[194] The use of

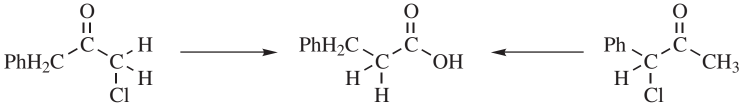
hydroxide ions or amines as bases leads to the free carboxylic acid (salt) or amide, respectively, instead of the ester. Cyclic α-halo ketones give ring contraction, as in the conversion of **65–66**.

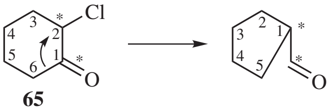
65 **66**

The reaction has also been carried out on α-hydroxy ketones[195] and on α,β-epoxy ketones, which give β-hydroxy acids.[196] The fact that an epoxide gives a reaction analogous to a halide indicates that the oxygen and halogen are leaving groups in a nucleophilic substitution step.



67 **68** **69**

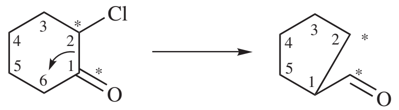
Through the years, the mechanism[197] of the Favorskii rearrangement has been the subject of much investigation; at least five different mechanisms have been proposed. However, the finding[198] that **67** and **68** *both* give **69** (this behavior is typical) shows that any mechanism where the halogen leaves and R^1 takes its place is invalid, since in such a case **67** would be expected to give **69** (with $PhCH_2$ migrating), but **68** should give PhCHMeCOOH (with CH_3 migrating). That is, in the case of **68**, it was PhCH that migrated and not methyl. Another important result was determined by radioactive labeling. **65**, in which C-1 and C-2 were equally labeled with ^{14}C, was converted to **66**. The product was found to contain 50% of the label on the carbonyl carbon, 25% on C-1, and 25% on C-2.[199] Now the carbonyl carbon, which originally carried half of the radioactivity, still had this much, so the rearrangement did not directly affect *it*. However, if the C-6 carbon had migrated to C-2, the other half of the radioactivity would be only on C-1 of the product:



65

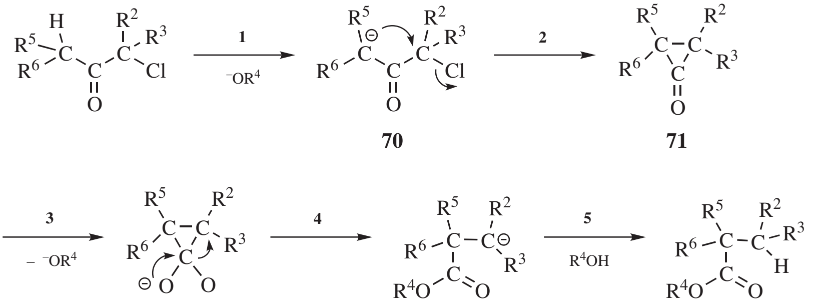
[195]Craig, J.C.; Dinner, A.; Mulligan, P.J. *J. Org. Chem.* ***1972***, *37*, 3539.
[196]See, for example, House, H.O.; Gilmor, W.F. *J. Am. Chem. Soc.* ***1961***, *83*, 3972; Mouk, R.W.; Patel, K.M.; Reusch, W. *Tetrahedron* ***1975***, *31*, 13.
[197]For a review of the mechanism, see Baretta, A.; Waegell, B. *React. Intermed. (Plenum)* ***1982***, *2*, 527.
[198]McPhee, W.D.; Klingsberg, E. *J. Am. Chem. Soc.* ***1944***, *66*, 1132; Bordwell, F.G.; Scamehorn, R.G.; Springer, W.R. *J. Am. Chem. Soc.* ***1969***, *91*, 2087.
[199]Loftfield, R.B. *J. Am. Chem. Soc.* ***1951***, *73*, 4707.

On the other hand, if the migration had gone the other way: If the C-2 carbon had migrated to C-6–then this half of the radioactivity would be found solely on C-2 of the product:



65

The fact that C-1 and C-2 were found to be equally labeled showed that *both migrations occurred*, with equal probability. Since C-2 and C-6 of **65** are not equivalent, this means that there must be a symmetrical intermediate.[200] The type of intermediate that best fits the circumstances is a cyclopropanone,[201] and the mechanism (for the general case) is formulated (replacing R^1 of our former symbolism with CHR^5R^6, since it is obvious that for this mechanism an α hydrogen is required on the non-halogenated side of the carbonyl):



70 **71**

The intermediate corresponding to **71** in the case of **65** is a symmetrical compound, and the three-membered ring can be opened with equal probability on either side of the carbonyl, accounting for the results with ^{14}C. In the general case, **71** is not symmetrical and should open on the side that gives the more stable carbanion.[202] This accounts for the fact that **67** and **68** give the same product. The intermediate in both cases is **70**, which always opens to give the carbanion stabilized by resonance. The cyclopropanone intermediate (**71**) has been isolated in the case where $R^2 = R^5 = t$-Bu and $R^3 = R^6 = H$,[203] and it

[200]A preliminary migration of the chlorine from C-2 to C-6 was ruled out by the fact that recovered **65** had the same isotopic distribution as the starting **65**.

[201]Although cyclopropanones are very reactive compounds, several of them have been isolated. For reviews of cyclopropanone chemistry, see Wasserman, H.H.; Clark, G.M.; Turley, P.C. *Top. Curr. Chem.* ***1974***, *47*, 73; Turro, N.J. *Acc. Chem. Res.* ***1969***, *2*, 25.

[202]Factors other than carbanion stability (including steric factors) may also be important in determining which side of an unsymmetrical **71** is preferentially opened. See, for example, Rappe, C.; Knutsson, L. *Acta Chem. Scand.*, ***1967***, *21*, 2205; Rappe, C.; Knutsson, L.; Turro, N.J.; Gagosian, R.B. *J. Am. Chem. Soc.* ***1970***, *92*, 2032.

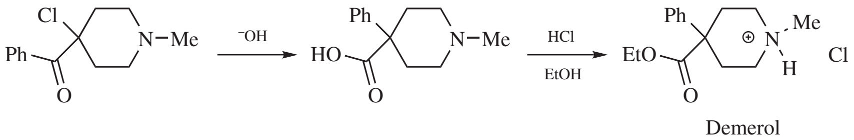
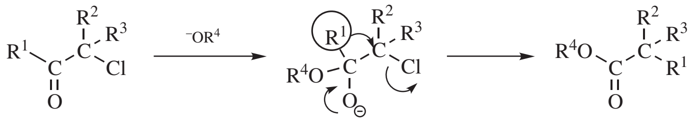
has also been trapped.[204] Also, cyclopropanones synthesized by other methods have been shown to give Favorskii products on treatment with NaOMe or other bases.[205]

The mechanism discussed is in accord with all the facts when the halo ketone contains an α hydrogen on the other side of the carbonyl group. However, ketones that do not have a hydrogen there also rearrange to give the same type of product. This is usually called the *quasi-Favorskii rearrangement*. An example is found in the preparation of Demerol:[206]



The quasi-Favorskii rearrangement obviously cannot take place by the cyclopropanone mechanism. The mechanism that is generally accepted (called the *semibenzilic mechanism*[207]) is a base-catalyzed pinacol



rearrangement-type mechanism similar to that of **18-6**. This mechanism requires inversion at the migration terminus and this has been found.[208] It has been shown that even where there *is* an appropriately situated a hydrogen, the semibenzilic mechanism may still operate.[209]

An interesting analog of the Favorskii rearrangement treats a ketone, such as 4-*tert*-butylcyclohexanone, without an α-halogen with $Tl(NO_3)_3$ to give 3-*tert*-butylcyclopentane-1-carboxylic acid.[210]

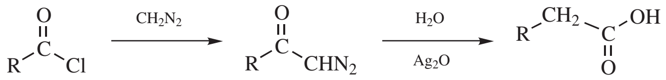
18-8 The Arndt–Eistert Synthesis



In the *Arndt–Eistert synthesis*, an acyl halide is converted to a carboxylic acid with one additional carbon.[211] The first step of this process is reaction **16-89**. The actual rearrangement occurs in the second step on treatment of the diazo ketone with water and silver oxide or with silver benzoate and triethylamine. This rearrangement is called the *Wolff rearrangement*.[212] It is the best method of increasing a carbon chain by one if a *carboxylic acid* is available (**10-75** and **16-30** begin with alkyl halides). If an alcohol R'OH is used instead of water, the ester RCH_2COOR' is isolated directly.[213] Similarly, ammonia gives the amide. Other catalysts are sometimes used (e.g., colloidal platinum, copper, etc.), but occasionally the diazo ketone is simply heated or photolyzed in the presence of water, an alcohol, or ammonia, with no catalyst at all.[214] The photolysis method[215] often gives better results than the silver catalysis method. Of course, diazo ketones prepared in any other way also give the rearrangement.[216] The reaction is of wide scope. The R group may be alkyl or aryl and may contain many functional groups including unsaturation, but not including groups acidic enough to react with CH_2N_2 or diazo ketones (e.g., **10-5** and **10-19**). Sometimes the reaction is performed with other diazoalkanes (i.e., $R'CHN_2$) to give RCHR'COOH. The reaction has often been used for ring contraction of cyclic diazo ketones,[217] such as **72**.[218]

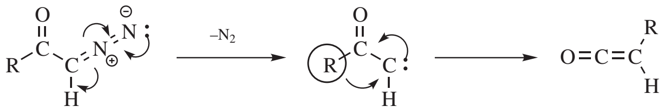
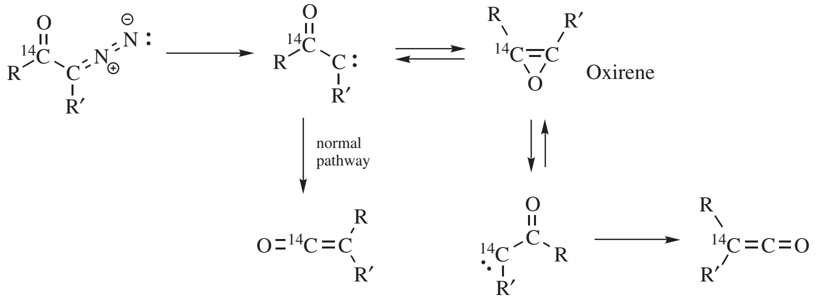
The mechanism is generally regarded as involving formation of a carbene.[219] It is the divalent carbon that has the open sextet and to which the migrating group brings its electron pair:



The actual product of the reaction is thus the ketene, which then reacts with water (**15-3**), an alcohol (**15-5**), or ammonia or an amine (**15-8**). Particularly stable ketenes[220] (e.g., $Ph_2C{=}C{=}O$) have been isolated and others have been trapped in other ways (e.g., as β-lactams,[221] **16-96**). The purpose of the catalyst is not well understood, though many suggestions have been made. This mechanism is strictly analogous to that of the Curtius rearrangement (**18-14**). Although the mechanism as shown above involves a free carbene and there is much evidence to support this,[222] it is also possible that at least in some cases the two steps are concerted and a free carbene is absent.

When the Wolff rearrangement is carried out photochemically, the mechanism is basically the same,[215] but another pathway can intervene. Some of the ketocarbene originally formed can undergo a carbene–carbene rearrangement, through an oxirene intermediate.[223] This was shown by ^{14}C labeling experiments, where



diazo ketones labeled in the carbonyl group gave rise to ketenes that bore the label at both C=C carbons.[224] In general, the smallest degree of scrambling (and thus of

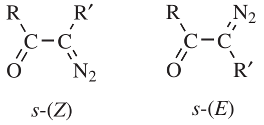
the oxirene pathway) was found when R′ = H. An intermediate believed to be an oxirene has been detected by laser spectroscopy.[225] The oxirene pathway is not found in the thermal Wolff rearrangement. It is likely that an excited singlet state of the carbene is necessary for the oxirene pathway to intervene.[226] In the photochemical process, ketocarbene intermediates, in the triplet state, have been isolated in an Ar matrix at 10–15 K, where they have been identified by UV–visible, IR, and esr spectra.[227] These intermediates went on to give the rearrangement via the normal pathway, with no evidence for oxirene intermediates.



The diazo ketone can exist in two conformations, called *s*-(*E*) and *s*-(*Z*). Studies have shown that Wolff rearrangement takes place preferentially from the *s*-(*Z*) conformation.[228]

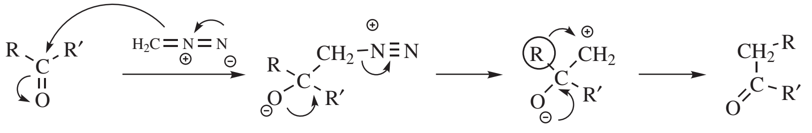
formation of an epoxide (**16-46**) is a side reaction. Although this reaction appears superficially to be similar to the insertion of carbenes into C–H bonds, **12-21** (and IUPAC names it as an insertion), the mechanism is quite different. This is a true rearrangement and no free carbene is involved. The first step is an addition to the C=O bond:



The betaine **73** can sometimes be isolated. As shown in **16-46**, intermediate **73** can also go to the epoxide. The evidence for this mechanism is summarized in the review by Gutsche.[230] Note that this mechanism is essentially the same as in the apparent "insertions" of oxygen (**18-19**) and nitrogen (**18-16**) into ketones.

Aldehydes give fairly good yields of methyl ketones; that is, hydrogen migrates in preference to alkyl. The most abundant side product is not the homologous aldehyde, but the epoxide. However, the yield of aldehyde at the expense of methyl ketone can be increased by the addition of methanol. If the aldehyde contains electron-withdrawing groups, the yield of epoxides is increased and the ketone is formed in smaller amounts, if at all. Ketones give poorer yields of homologous ketones. Epoxides are usually the predominant product here, especially when one or both R groups contain an electron-withdrawing group. The yield of ketones also decreases with increasing length of the chain. The use of a Lewis acid increases the yield of ketone.[234] Cyclic ketones,[235] three-membered[236] and larger, behave particularly well and give good yields of ketones with the ring expanded by one.[237] Aliphatic diazo compounds ($RCHN_2$ and R_2CN_2) are sometimes used instead of diazomethane, with the expected results.[238] Ethyl diazoacetate can be used analogously, in the presence of a Lewis acid or of triethyloxonium fluoroborate,[239] to

[234]For a review of homologations catalyzed by Lewis acids, see Müller, E.; Kessler, H.; Zeeh, B. *Fortschr. Chem. Forsch.* ***1966***, *7*, 128, see pp. 137–150.

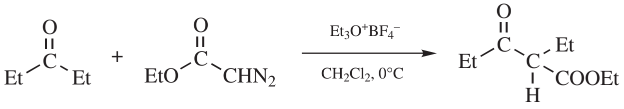
give a β-keto ester, such as **74**.



74

When unsymmetrical ketones were used in this reaction (with BF_3 as catalyst), the less highly substituted carbon preferentially migrated.[240] The reaction can be made regioselective by applying this method to the α-halo ketone, in which case only the other carbon migrates.[241] The ethyl diazoacetate procedure has also been applied to the acetals or ketals of α,β-unsaturated aldehydes and ketones.[242]

Bicyclic ketones can be expanded to form monocyclic ketones in the presence of certain reagents. Treatment of a bicyclo[4.1.0]hexan-4-one derivative with SmI_2 led to a cyclohexanone.[243] The SmI_2 also converts α-halomethyl cyclic ketones to the next larger ring ketone[244] and cyclic ketones to the next larger ring ketone in the presence of CH_2I_2.[245] α-Chloro-α-3-iodopropylcyclobutanones were converted to cycloheptanones using radical conditions (Bu_3SnH/AIBN).[246]

Another homologation reaction converts an aldehyde to its tosyl hydrazone, and subsequent reaction with an aldehyde and NaOEt/EtOH give a ketone.[247] The reaction of an aldehyde with vinyl acetate and barium hydroxide gives the homologated conjugated aldehyde.[248]

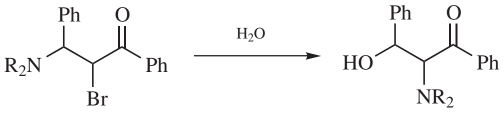
B. Carbon-to-Carbon Migrations of Other Groups

18-10 Migrations of Halogen, Hydroxyl, Amino, and so on

Hydroxy-de-bromo-*cine*-substitution, and so on



When a nucleophilic substitution is carried out on a substrate that has a neighboring group (p. 446) on the adjacent carbon, a cyclic intermediate can be generated

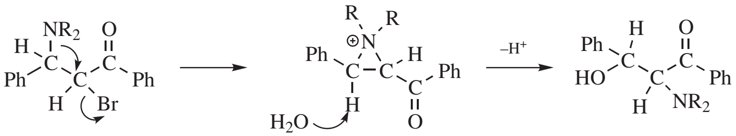
that is opened on the opposite side, resulting in migration of the neighboring group. In the example shown above (NR_2 = morpholino),[249] the reaction took place via an aziridinium salt **75** to give an α-amino-β-hydroxy ketone.

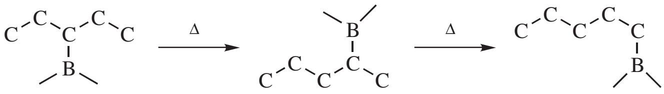


75

Sulfonate esters and halides can also migrate in this reaction.[250] α-Halo and α-acyloxy epoxides undergo ready rearrangement to α-halo and α-acyloxy ketones, respectively.[251] These substrates are very prone to rearrange, and often do so on standing without a catalyst, though in some cases an acid catalyst is necessary. The reaction is essentially the same as the rearrangement of epoxides shown in **18-2**, except that in this case halogen or acyloxy is the migrating group (as shown above; however, it is also possible for one of the R groups (alkyl, aryl, or hydrogen) to migrate instead, and mixtures are sometimes obtained).

18-11 Migration of Boron

Hydro,dialkylboro-interchange, and so on



Boranes are prepared by the reaction of $BH_3(B_2H_6)$ or an alkylborane with an alkene (**15-16**). When a nonterminal borane is heated at temperatures ranging from 100 to 200°C, the boron moves toward the end of the chain.[252] The reaction is catalyzed by small amounts of borane or other species containing B–H bonds.

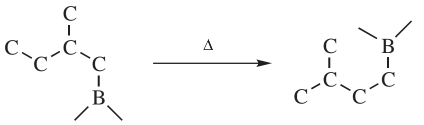
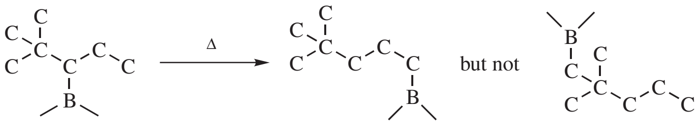
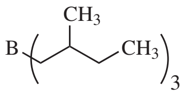
The boron can move past a branch, for example,



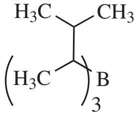
but not past a double branch, for example,



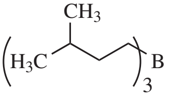
The reaction is an equilibrium: **76**, **77**, and **78** each gave a mixture containing ~40% **76**, 1% **77**, and 59% **78**. The migration can go quite a long distance. Thus $(C_{11}H_{23}CHC_{11}H_{23})_3B$ was completely converted to $(C_{23}H_{47})_3B$, involving a migration of 11 positions.[253] If the boron is on a cycloalkyl ring, it can move around



76



77

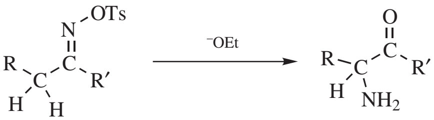


78

the ring; if any alkyl chain is also on the ring, the boron may move from the ring to the chain, ending up at the end of the chain.[254] The reaction is useful for the migration of double bonds in a controlled way (see **12-2**). The mechanism may involve a π complex, at least partially.[255]

18-12 The Neber Rearrangement

Neber oxime tosylate-amino ketone rearrangement



α-Amino ketones can be prepared by treatment of ketoxime tosylates with a base, such as ethoxide ion or pyridine.[256] This reaction is called the *Neber rearrangement*. The R group is usually aryl, though the reaction has been carried out with

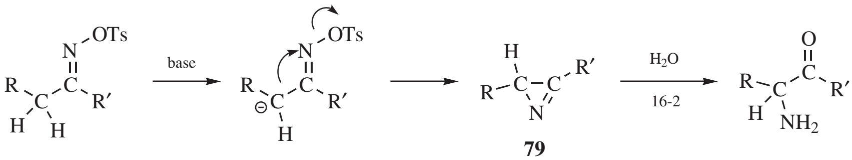
R = alkyl or hydrogen. The R′ group may be alkyl, or aryl but not hydrogen. The Beckmann rearrangement (**18-17**) and the abnormal Beckmann reaction (elimination to the nitrile, **17-30**) may be side reactions, although these generally occur in acid media. A similar rearrangement is given by *N,N*-dichloroamines of the type $RCH_2CH(NCl_2)R'$, where the product is also $RCH(NH_2)COR'$.[257] The mechanism of the Neber rearrangement is via an azirine intermediate **79**.[258]

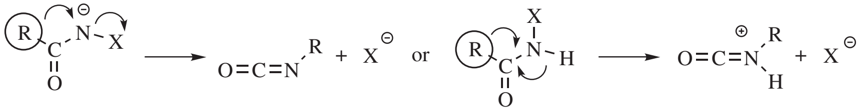


The best evidence for this mechanism is that the azirine intermediate has been isolated.[258,259] In contrast to the Beckmann rearrangement, this one is sterically indiscriminate:[260] Both a syn and an anti ketoxime give the same product. The mechanism as shown above consists of three steps. However, it is possible that the first two steps are concerted, and it is also possible that what is shown as the second step is actually two steps: loss of OTs to give a nitrene, and formation of the azirine. In the case of the dichloroamines, HCl is first lost to give $RCH_2C(=NCl)R'$, which then behaves analogously.[261] *N*-Chloroimines prepared in other ways also give the reaction.[262]

OS **V**, 909; **VII**, 149.

C. Carbon-to-Nitrogen Migrations of R and AR

The reactions in this group are nucleophilic migrations from a carbon to a nitrogen atom. In each case the nitrogen atom either has six electrons in its outer shell (and thus invites the migration of a group carrying an electron pair) or else loses a nucleofuge concurrently with the migration (p. 1560). Reactions **18-13–18-16** are used to prepare amines from acid derivatives. Reactions **18-16** and **18-17** are used to prepare amines from ketones. The mechanisms of **18-13–18-16** (with carboxylic acids) are very similar and follow one of two patterns:



[257]Baumgarten, H.E.; Petersen, H.E. *J. Am. Chem. Soc.* ***1960***, *82*, 459, and references cited therein.

[258]Cram, D.J.; Hatch, M.J. *J. Am. Chem. Soc.* ***1953***, *75*, 33; Hatch, M.J.; Cram, D.J. *J. Am. Chem. Soc.* ***1953***, *75*, 38.

[259]Neber, P.W.; Burgard, A. *Liebigs Ann. Chem.* ***1932***, *493*, 281; Parcell, R.F. *Chem. Ind. (London)* ***1963***, 1396.

[260]House, H.O.; Berkowitz, W.F. *J. Org. Chem.* ***1963***, *28*, 2271.

[261]For example, see Nakai, M.; Furukawa, N.; Oae, S. *Bull. Chem. Soc. Jpn.* ***1969***, *42*, 2917.

[262]Baumgarten, H.E.; Petersen, J.M.; Wolf, D.C. *J. Org. Chem.* ***1963***, *28*, 2369.

Some of the evidence[263] is (*1*) configuration is retained in R (p. 1563); (*2*) the kinetics are first order; (*3*) intramolecular rearrangement is shown by labeling; and (*4*) no rearrangement occurs *within* the migrating group, for example, a neopentyl group on the carbon of the starting material is still a neopentyl group on the nitrogen of the product.

In many cases, it is not certain whether the nucleofuge X is lost first, creating an intermediate nitrene[264] or nitrenium ion, or whether migration and loss of the nucleofuge are simultaneous, as shown above.[265] It is likely that both possibilities can exist, depending on the substrate and reaction conditions.

18-13 The Hofmann Rearrangement

Bis(hydrogen)-(2/ 1/*N*-alkyl)-*migro*-detachment (formation of isocyanate)

$$RCONH_2 + NaOBr \longrightarrow R{-}N{=}C{=}O \xrightarrow[\textbf{16-2}]{\text{hydrolysis}} RNH_2$$

In the *Hofmann rearrangement*, an unsubstituted amide is treated with sodium hypobromite (or sodium hydroxide and bromine, which is essentially the same thing) to give a primary amine that has one carbon fewer than the starting amide.[266] The actual product is the isocyanate, but this compound is seldom isolated[267] since it is usually hydrolyzed under the reaction conditions. The R group may be alkyl or aryl, but if it is an alkyl group of more than about six or seven carbons, low yields are obtained unless Br_2 and NaOMe are used instead of Br_2 and NaOH.[268] Another modification uses NBS/NaOMe.[269] Under these conditions the product of addition to the isocyanate is the carbamate RNHCOOMe (**16-8**), which is easily isolated or can be hydrolyzed to the amine. Side reactions when NaOH is the base are formation of ureas RNHCONHR and acylureas RCONHCONHR by addition, respectively, of RNH_2 and $RCONH_2$ to RNCO (**16-20**). If acylureas are desired, they can be made the main products by using only one-half of the usual quantities of Br_2 and NaOH. Another side product, but only from primary R, is the nitrile derived from oxidation of RNH_2 (**19-5**). Imides react to give amino acids, for example, phthalimide gives *o*-aminobenzoic acid. α-Hydroxy and α-halo amides give aldehydes and ketones by way of the unstable α-hydroxy- or α-haloamines. However, a side product with an α-halo amide is a *gem*-dihalide. Ureas analogously give hydrazines.

[263]For a discussion of this mechanism and the evidence for it, see Smith, P.A.S., in de Mayo, P. *Molecular Rearrangements*, Vol. 1, Wiley, NY, ***1963***, Vol. 1, pp. 258–550.

[264]For a review of rearrangements involving nitrene intermediates, see Boyer, J.H. *Mech. Mol. Migr.* ***1969***, *2*, 267. See also, Ref. 282.

[265]The question is discussed by Lwowski, W., in Lwowski *Nitrenes*, Wiley, NY, ***1970***, pp. 217–221.

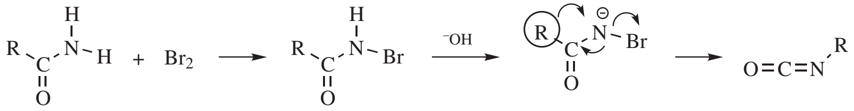
[266]For a review, see Wallis, E.S.; Lane, J.F. *Org. React.* ***1946***, *3*, 267.

[267]If desired, the isocyanate can be isolated by the use of phase-transfer conditions: see Sy, A.O.; Raksis, J.W. *Tetrahedron Lett.* ***1980***, *21*, 2223.

[268]For an example of the use of this method at low temperatures, see Radlick, P.; Brown, L.R. *Synthesis* ***1974***, 290.

[269]Huang, X.; Keillor, J.W. *Tetrahedron Lett.* ***1997***, *38*, 313.

The mechanism follows the pattern outlined on p. 1606.



80

The first step is an example of **12-52** and intermediate *N*-halo amides (**80**) have been isolated. In the second step, **80** lose a proton to the base. Compound **80** is acidic because of the presence of two electron-withdrawing groups (acyl and halo) on the nitrogen. It is possible that the third step is actually two steps: loss of bromide to form a nitrene, followed by the actual migration, but most of the available evidence favors the concerted reaction.[270] A similar reaction can be effected by the treatment of amides with lead tetraacetate.[271] Among other reagents that convert $RCONH_2$ to RNH_2 (R = alkyl, but not aryl) are phenyliodosyl bis(trifluoroacetate) $PhI(OCOCF_3)_2$[272] and hydroxy(tosyloxy)iodobenzene PhI(OH)OTs.[273] A mixture of NBS, $Hg(OAc)_2$, and R'OH is one of several reagent mixtures that convert an amide $RCONH_2$ to the carbamate RNHCOOR' (R = primary, secondary, or tertiary alkyl or aryl) in high yield.[274] A mixture of NBS and DBU (p. 1132) in methanol gives the carbamate,[275] as does electrolysis in methanol.[276]

A variation of the Hofmann rearrangement treated a β-hydroxy primary amide with $PhI(O_2CCF_3)_2$ in aqueous acetonitrile, giving an isocyanate via –CON–I, which reacts with the hydroxyl group intramolecularly to give a cyclic carbamate.[277] Note that carbamates are converted to isocyanates by heating with Montmorillonite K10.[278]

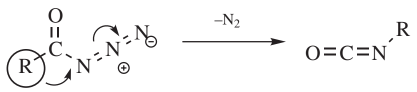
The *Curtius rearrangement* involves the pyrolysis of acyl azides to yield isocyanates.[279] The reaction gives good yields of isocyanates, since no water is present to hydrolyze them to the amine. Of course, they can be subsequently hydrolyzed, and indeed the reaction *can* be carried out in water or alcohol, in which case the products are amines, carbamates, or acylureas, as in **18-13**.[280] This is a very general reaction and can be applied to almost any carboxylic acid: aliphatic, aromatic, alicyclic, heterocyclic, unsaturated, and containing many functional groups. Acyl azides can be prepared as in **10-43** or by treatment of acylhydrazines (hydrazides) with nitrous acid (analogous to **12-49**). The Curtius rearrangement is catalyzed by Lewis or protic acids, but these are usually not necessary for good results.

The mechanism is similar to that in **18-13** to give an isocyanate. Also note the exact analogy between this reaction and **18-8**. However, in this case, there is no evidence for a free nitrene and it is probable that the steps are concerted.[281]



Alkyl azides can be similarly pyrolyzed to give imines, in an analogous reaction:[282]

$$R_3CN_3 \xrightarrow{\Delta} R_2C{=}NR$$

The R groups may be alkyl, aryl, or hydrogen, though if hydrogen migrates, the product is the unstable $R_2C{=}NH$. The mechanism is essentially the same as that of the Curtius rearrangement. However, in pyrolysis of tertiary alkyl azides, there is evidence that free alkyl nitrenes are intermediates.[283] The reaction can also be carried out with acid catalysis, in which case lower temperatures can be used, though the acid may hydrolyze the imine (**16-2**). Cycloalkyl azides give

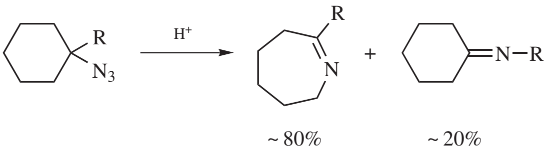
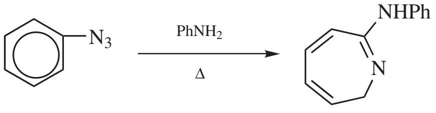
ring expansion.[284]



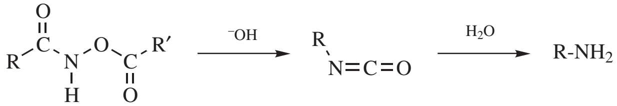
Aryl azides also give ring expansion on heating, for example,[285]



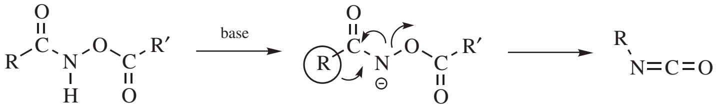
OS **III**, 846; **IV**, 819; **V**, 273; **VI**, 95, 910. Also see, OS **VI**, 210.

18-15 The Lossen Rearrangement

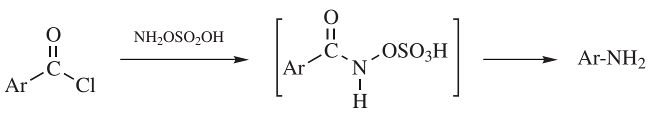
Hydro,acetoxy-(2/ → 1*N*-alkyl)-*migro*-detachment



The *O*-acyl derivatives of hydroxamic acids[286] give isocyanates when treated with bases or sometimes even just on heating, in a reaction known as the *Lossen rearrangement*.[287] The mechanism is similar to that of **18-13** and **18-14**:



In a similar reaction, aromatic acyl halides are converted to amines in one laboratory step by treatment with hydroxylamine-*O*-sulfonic acid.[288]



A chiral Lossen rearrangement is known.[289]

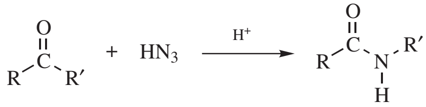
18-16 The Schmidt Reaction

$$RCOOH + HN_3 \xrightarrow{H^+} R{-}N{=}C{=}O \xrightarrow{H_2O} RNH_2$$

There are actually three reactions called by the name *Schmidt reaction*, involving the addition of hydrazoic acid to carboxylic acids, aldehydes and ketones, and alcohols and alkenes.[290] The most common is the reaction with carboxylic acids, illustrated above.[291] Sulfuric acid is the most common catalyst, but Lewis acids have also been used. Good results are obtained for aliphatic R, especially for long chains. When R is aryl, the yields are variable, being best for sterically hindered compounds like mesitoic acid. This method has the advantage over **18-13** and **18-14** in that there is just one laboratory step from the acid to the amine, but conditions are more drastic.[292] Under the acid conditions employed, the isocyanate is virtually never isolated.

The reaction between a ketone and hydrazoic acid is a method for "insertion" of NH between the carbonyl group and one R group, converting a ketone into an amide.[293]



Either or both of the R groups may be aryl. In general, dialkyl ketones and cyclic ketones react more rapidly than alkyl aryl ketones, and these more rapidly than diaryl ketones. The latter require sulfuric acid and do not react in concentrated HCl, which is strong enough for dialkyl ketones. Dialkyl and cyclic ketones react sufficiently faster than diaryl or aryl alkyl ketones or carboxylic acids or alcohols so that these functions may be present in the same molecule without interference. Cyclic ketones give lactams:[294]

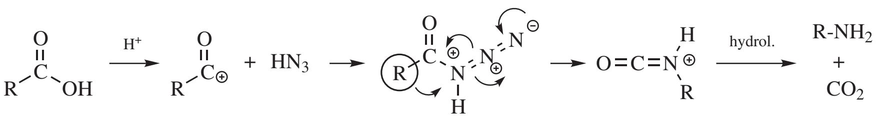
[294]For a review with respect to bicyclic ketones, see Krow, G.R. *Tetrahedron* ***1981***, *37*, 1283.

With alkyl aryl ketones, it is the aryl group that generally migrates to the nitrogen, except when the alkyl group is bulky.[295] The reaction has been applied to a few aldehydes, but rarely. With aldehydes the product is usually the nitrile (**16-16**). Even with ketones, conversion to the nitrile is often a side reaction, especially with the type of ketone that gives **17-30**. A useful variation of the Schmidt reaction treats a cyclic ketone with an alkyl azide (RN_3)[296] in the presence of $TiCl_4$, generating a lactam.[297] An intramolecular Schmidt reaction gives bicyclic amines by treatment of a cyclic alkene having a pendant azidoalkyl group with $Hg(ClO_4)_2$, and then $NaBH_4$.[298] Another variation treats a silyl enol ether of a cyclic ketone with $TMSN_3$ and photolyzes the product with UV light to give a lactam.[299] αAzido cyclic ketones rearrangement to lactams under radical conditions (Bu_3SnH/AIBN).[300]

Alcohols and alkenes react with HN_3 to give alkyl azides,[301] which in the course of reaction rearrange in the same way as discussed in reaction **18-14**.[282] The Mitsunobu reaction (**10-17**) can be used to convert alcohols to alkyl azides, and an alternative reagent for azides, $(PhO)_2PON_3$, for use in the Mitsunobu is now available.[302]

There is evidence that the mechanism with carboxylic acids[293] is similar to that of **18-14**, except that it is the protonated azide that undergoes the rearrangement:[303]



The first step is the same as that of the $A_{AC}1$ mechanism (**16-59** which explains why good results are obtained with hindered substrates. The mechanism with ketones

[295]Exceptions to this statement have been noted in the case of cyclic aromatic ketones bearing electron-donating groups in ortho and para positions: Bhalerao, U.T.; Thyagarajan, G. *Can. J. Chem.* ***1968***, *46*, 3367; Tomita, M.; Minami, S.; Uyeo, S. *J. Chem. Soc. C* ***1969***, 183.

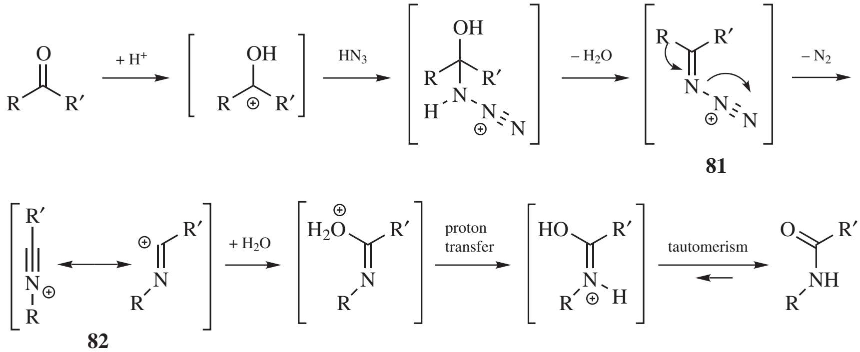
involves formation of a nitrilium ion **82**, which reacts with water.



The intermediates **81** have been independently generated in aqueous solution.[304] Note the similarity of this mechanism to those of "insertion" of CH_2 (**18-9**) and of O (**18-19**). The three reactions are essentially analogous, both in products and in mechanism.[293,305] Also note the similarity of the latter part of this mechanism to that of the Beckmann rearrangement (**18-17**).

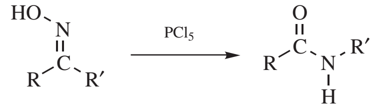
18-17 The Beckmann Rearrangement

Beckmann oxime-amide rearrangement



When oximes are treated with PCl_5 or a number of other reagents, they rearrange to substituted amides in a reaction called the *Beckmann rearrangement*.[306] Among other reagents used have been concentrated H_2SO_4, formic acid, liquid SO_2, $SOCl_2$,[307] silica gel,[308] MoO_3 on silica gel,[309] $RuCl_3$,[310] $Y(OTf)_3$,[311]

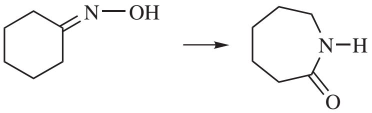
HCl–HOAc-Ac_2O, $POCl_3$,[312] $BiCl_3$,[313] neat with $FeCl_3$,[314] and polyphosphoric acid.[315] The reaction has been done in supercritical water[316] and in ionic liquids.[317] A polymer-bound Beckman rearrangement has been reported.[318] Simply heating the oxime of benzophenone neat leads to *N*-phenyl benzamide.[319] The oximes of cyclic ketones give ring enlargement and form the lactam,[320] as in the formation of caprolactam (**83**) from the oxime of cyclohexanone. Heating an oxime of a cyclic ketone, *neat*, with $AlCl_3$ also leads to the lactam,[321] as does microwave irradiation of an oxime on Montmorillonite K10 clay.[322] Other solvent-free reactions are known.[323] Treatment of a cyclic ketone with NH_2OSO_3H on silica gel followed by microwave irradiation also gives the lactam.[324] Cyclic ketones can be converted directly to lactams in one laboratory step by treatment with NH_2OSO_2OH and formic acid (**16-14** takes place first, then the Beckmann rearrangement).[325] Heating a ketone with hydroxylamine HCl and oxalic acid also gives the amide.[326] Note that the reaction of an imine with BF_3•OEt_2 and *m*-chloroperoxybenzoic acid leads to a formamide.[327]



83

Of the groups attached to the carbon of the C=N unit, the one that migrates in the Beckman rearrangement is generally the one anti to the hydroxyl, and this is

often used as a method of determining the configuration of the oxime. However, it is not unequivocal. It is known that with some oximes the syn group migrates and that with others, especially where R and R′ are both alkyl, mixtures of the two possible amides are obtained. However, this behavior does not necessarily mean that the syn group actually undergoes migration. In most cases, the oxime undergoes isomerization under the reaction conditions *before* migration takes place.[328] The scope of the reaction is quite broad and R and R′ may be alkyl, aryl, or hydrogen. However, hydrogen very seldom *migrates*, so the reaction is not generally a means of converting aldoximes to unsubstituted amides ($RCONH_2$). This latter conversion can be accomplished, however, by treatment of the aldoxime with nickel acetate under neutral conditions[329] or by heating the aldoxime for 60 h at 100°C after it has been adsorbed onto silica gel.[330] As in the case of the Schmidt rearrangement, when the oxime is derived from an alkyl aryl ketone, it is generally the aryl group that preferentially migrates.[331]

Not only do oximes undergo the Beckmann rearrangement, but so also do esters of oximes with many acids, organic and inorganic. A side reaction with many substrates is the formation of nitriles (the "abnormal" Beckmann rearrangement, **17-30**). The other reagents convert OH to an ester leaving group (e.g., $OPCl_4$ from PCl_5 and OSO_2OH from concentrated H_2SO_4[332]). The *O*-carbonates of imines, such as $Ph_2C{=}N{-}OCO_2Et$, react with $BF_3{\bullet}OEt_2$ to give the corresponding amide, in this case *N*-phenyl benzamide.[333]

In the first step of the mechanism, the OH group is converted by the reagent to a better leaving group, for example, proton acids convert it to OH_2^+. After that, the mechanism[334] follows a course analogous to that for the Schmidt reaction of ketones (**18-16**) from the formation of nitrilium ion **82** on:[335] Alternatively, the attack on **82** can be by the leaving group, if different from H_2O. For example, when PCl_5 is used to induce the reaction, a $N{-}O{-}PCl_4$ species is formed, which generates **82**. Intermediates of the form **82** have been detected by nmr and uv spectroscopy.[336] The rearrangement has also been found to take place by a different mechanism, involving formation of a nitrile by fragmentation, and then addition by

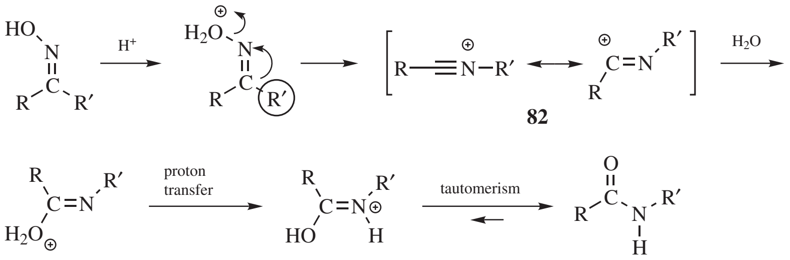
a Ritter reaction (**16-91**).[337] Beckmann rearrangements have also been carried out photochemically.[338]



If the rearrangement of oxime sulfonates is induced by organoaluminum reagents,[339] the nitrilium ion intermediate **82** is captured by the nucleophile originally attached to the Al. By this means an oxime can be converted to an imine, an imino thioether (R–N=C–SR), or an imino nitrile (R–N=C–CN).[340] In the last case, the nucleophile comes from added trimethylsilyl cyanide. The imine-producing reaction can also be accomplished with a Grignard reagent in benzene or toluene.[341]

In a related reaction, treatment of spirocyclic oxaziridines with MnCl(TPP)[342] or photolysis[343] leads to a lactam.

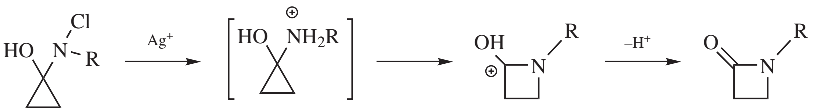
rearrangement when solvolyzed in the presence of silver nitrate.[344] This reaction is similar to the Wagner–Meerwein rearrangement (**18-1**) and is initiated by the silver-catalyzed departure of the chloride ion.[345] Similar reactions have been used for ring expansions and contractions, analogous to those discussed for reaction **18-3**.[346] An example is the conversion of 1-(*N*-chloroamino)cyclopropanols to β-lactams.[347] Methyl prolinate was converted to the lactam 2-piperidone upon treatment with SmI_2 and pivalic acid–THF.[348]



The name *Stieglitz rearrangement* is generally applied to the rearrangements of trityl *N*-haloamines and

$$Ar_3CNHX \xrightarrow{\text{base}} Ar_2C{=}NAr$$

$$Ar_3CNHOH \xrightarrow{PCl_5} Ar_2C{=}NAr$$

hydroxylamines. These reactions are similar to the rearrangements of alkyl azides (**18-14**), and the name Stieglitz rearrangement is also given to the rearrangement of trityl azides. Another similar reaction is the rearrangement undergone by tritylamines when treated with lead tetraacetate:[349]

$$Ar_3CNH_2 \xrightarrow{Pb(OAc)_4} Ar_2C{=}NAr$$

The treatment of ketones with peroxyacids, such as peroxybenzoic or peroxyacetic acid, or with other peroxy compounds in the presence of acid catalysts, gives carboxylic esters by "insertion" of oxygen[351] and the carboxylic acid parent of the peroxyacid as a by-product. The reaction is called the *Baeyer–Villiger rearrangement*.[352] A particularly good reagent is peroxytrifluoroacetic acid. Reactions with this reagent are rapid and clean, giving high yields of product, though it is often necessary to add a buffer, such as Na_2HPO_4, to prevent transesterification of the product with trifluoroacetic acid that is also formed during the reaction. The reaction is often applied to cyclic ketones to give lactones.[353] Hydrogen peroxide has been used to convert cyclic ketones to lactones using a catalytic amount of $MeReO_3$[354] or a diselenide catalyst.[355] Hydrogen peroxide and a $MeReO_3$ catalyst has been used in an ionic liquid.[356] Transition-metal catalysts have been used with peroxyacids to facilitate the oxidation.[357] Hydrogen peroxide and $PhAsO_3H_2$ in hexafluoro-1-propanol can be used.[358] Polymer-supported peroxy acids have been used,[359] and solvent-free Bayer–Villiger reactions are known.[360] Enantioselective synthesis[361] of chiral lactones from achiral ketones has been achieved by the use of enzymes[362]

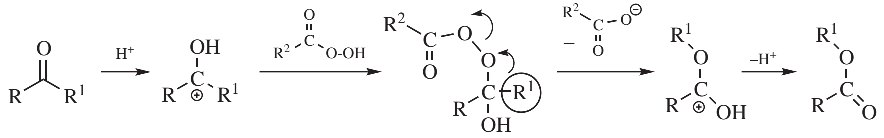
and other asymmetric reactions are known.[363] Oxidation of chiral substrates with *m*-chloroperoxybenzoic acid (mcpba) also leads to chiral lactones.[364]

For acyclic compounds, R′ must usually be secondary, tertiary, or vinylic, although primary R′ has been rearranged with peroxytrifluoroacetic acid,[365] with BF_3–H_2O_2,[366] and with $K_2S_2O_8$–H_2SO_4.[367] For unsymmetrical ketones the approximate order of migration is tertiary alkyl > secondary alkyl, aryl > primary alkyl > methyl. Since the methyl group has a low migrating ability, the reaction provides a means of cleaving a methyl ketone R'COMe to produce an alcohol or phenol (R'OH) (by hydrolysis of the ester R'OCOMe). The migrating ability of aryl groups is increased by electron-donating and decreased by electron-withdrawing substituents.[368] There is a preference of anti over gauche migration.[369] Enolizable β-diketones do not react. α-Diketones can be converted to anhydrides.[370] With aldehydes, migration of hydrogen gives the carboxylic acid, and this is a way of accomplishing **19-23**. Migration of the other group would give formates, but this seldom happens, though aryl aldehydes have been converted to formates with H_2O_2 and a selenium compound[371] (see also the Dakin reaction in **19-11**).

The mechanism[372] is similar to those of the analogous reactions with hydrazoic acid (**18-16** with ketones) and diazomethane (**18-8**):



One important piece of evidence for this mechanism was that benzophenone–^{18}O gave ester entirely labeled in the carbonyl oxygen, with none in the alkoxyl oxygen.[373] Carbon-14 isotope-effect studies on acetophenones have shown that

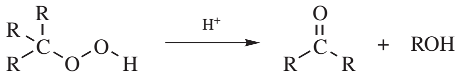
migration of aryl groups takes place in the rate-determining step,[374] demonstrating that migration of Ar is concerted with departure of $OCOR^2$.[375] It is hardly likely that migration would be the slow step if the leaving group departed first to give an ion with a positive charge on an oxygen atom, which would be a highly unstable species.

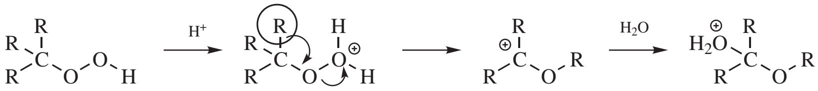
18-20 Rearrangement of Hydroperoxides

C-Alkyl-*O*-hydroxy-elimination



Hydroperoxides (R = alkyl, aryl, or hydrogen) can be cleaved by proton or Lewis acids in a reaction whose principal step is a rearrangement.[376] The reaction has also been applied to peroxy esters ($R_3COOCOR'$), but less often. When aryl and alkyl groups are both present, migration of aryl dominates. It is not necessary actually to prepare and isolate hydroperoxides. The reaction takes place when the alcohols are treated with H_2O_2 and acids. Migration of an alkyl group of a primary hydroperoxide provides a means for converting an alcohol to its next lower homolog ($RCH_2OOH \rightarrow CH_2{=}O + ROH$).

The mechanism is as follows:[377]



72 84

The last step is hydrolysis of the unstable hemiacetal. Alkoxycarbocation intermediates (**84**, R = alkyl) have been isolated in super acid solution[378] at

[374]Palmer, B.W.; Fry, A. *J. Am. Chem. Soc.* ***1970***, *92*, 2580. See also, Mitsuhashi, T.; Miyadera, H.; Simamura, O. *Chem. Commun.* ***1970***, 1301. For secondary isotope-effect studies, see Winnik, M.A.; Stoute, V.; Fitzgerald, P. *J. Am. Chem. Soc.* ***1974***, *96*, 1977.

[375]In some cases, the rate-determining step has been shown to be the addition of peracid to the substrate (see, e.g., Ogata, Y.; Sawaki, Y. *J. Org. Chem.* ***1972***, *37*, 2953). Even in these cases it is still highly probable that migration is concerted with departure of the nucleofuge.

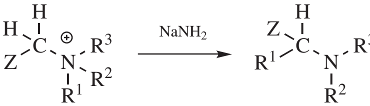
low temperatures, and their structures proved by nmr.[379] The protonated hydroperoxides could not be observed in these solutions, evidently reacting immediately on formation.

OS **V**, 818.

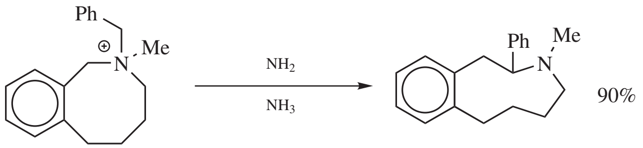
E. Nitrogen-to-Carbon, Oxygen-to-Carbon, and Sulfur-to-Carbon Migration

18-21 The Stevens Rearrangement

Hydron-(2/*N* → 1/alkyl)-*migro*-detachment



In the *Stevens rearrangement*, a quaternary ammonium salt containing an electron-withdrawing group Z on one of the carbons attached to the nitrogen is treated with a strong base (e.g., NaOR or $NaNH_2$) to give a rearranged tertiary amine. The Z group may be RCO, ROOC, or phenyl.[380] The most common migrating groups are allylic, benzylic, benzhydryl, 3-phenylpropargyl, and phenacyl, though even methyl migrates to a sufficiently negative center.[381] When an allylic group migrates, it may or may not involve an allylic rearrangement within the migrating group (see **18-35**), depending on the substrate and reaction conditions. The reaction has been used for ring enlargement,[382] for example:



The mechanism has been the subject of much study.[383] That the rearrangement is intramolecular was shown by crossover experiments, by ^{14}C labeling,[384] and by the

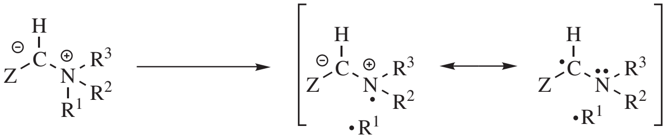
fact that retention of configuration is found at R^1.[385] The first step is loss of the acidic proton to give the ylid **85**, which has been isolated.[386] The finding[387] that CIDNP spectra[388] could be obtained in many instances shows that in these cases the product is formed directly from a free-radical precursor. The following radical pair mechanism was proposed:[389]

Mechanism *a*

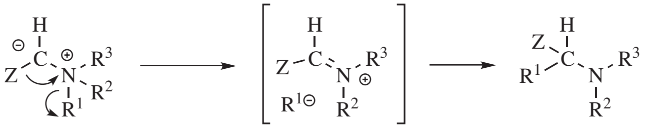


85

Solvent cage

The radicals do not drift apart because they are held together by the solvent cage. According to this mechanism, the radicals must recombine rapidly in order to account for the fact that R^1 does not racemize. Other evidence in favor of mechanism *a* is that in some cases small amounts of coupling products (R^1–R^1) have been isolated,[390] which would be expected if some •R^1 leaked from the solvent cage. However, not all the evidence is easily compatible with mechanism *a*.[391] It is possible that another mechanism (*b*) similar to mechanism *a*, but involving

Mechanism *b*



85

Solvent cage

ion pairs in a solvent cage instead of radical pairs, operates in some cases. A third possible mechanism would be a concerted 1,2-shift,[392] but the orbital symmetry

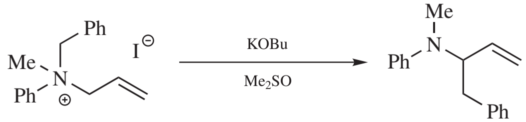
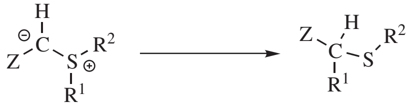
principle requires that this take place with inversion at R^1.[393] (see p. 1654.) Since the actual migration takes place with retention, it cannot, according to this argument, proceed by a concerted mechanism. However, in the case where the migrating group is allylic, a concerted mechanism can also operate (**18-35**). An interesting finding compatible with all three mechanisms is that optically active allylbenzylmethylphenylammonium iodide (asymmetric nitrogen, see p. 142) gave an optically active product:[394]



The *Sommelet–Hauser rearrangement* competes when Z is an aryl group (see **13-31**). *Hofmann elimination* competes when one of the R groups contains a β hydrogen atom (**17-7** and **17-8**).

Sulfur ylids containing a Z group give an analogous rearrangement, often also referred to as a Stevens



rearrangement.[395] In this case too, there is much evidence (including CIDNP) that a radical-pair cage mechanism is operating,[396] except that when the migrating group is allylic, the mechanism may be different (see **18-35**). Another reaction with a similar mechanism[397] is the *Meisenheimer rearrangement*,[398] in which certain tertiary

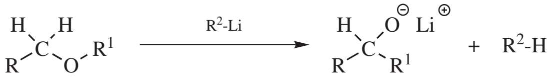
amine oxides rearrange on heating to give substituted hydroxylamines.[399] The migrating group R^1 is almost always allylic or benzilic.[400] R^2 and R^3 may be alkyl or aryl, but if one of the R groups contains a β hydrogen, Cope elimination (**17-9**) often competes. In a related reaction, when 2-methylpyridine *N*-oxides are treated with trifluoroacetic anhydride, the *Boekelheide reaction* occurs to give 2-hydroxymethylpyridines.[401]

Certain tertiary benzylic amines, when treated with BuLi, undergo a rearrangement analogous to the Wittig rearrangement (**18-22**), for example, $PhCH_2NPh_2 \rightarrow Ph_2CHNHPh$.[402] Only aryl groups migrate in this reaction.

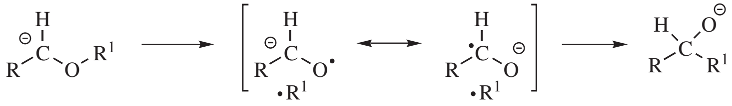
Isocyanides, when heated in the gas phase or in nonpolar solvents, undergo a 1,2-intramolecular rearrangement to nitriles: RNC → RCN.[403] In polar solvents the mechanism is different.[404]

18-22 The Wittig Rearrangement[405]

Hydron-(2/*O* → 1/alkyl)-*migro*-detachment



The rearrangement of ethers with alkyllithium reagents is called the *Wittig rearrangement* (not to be confused with the Wittig reaction, **16-44**) and is similar to **18-21**.[380] However, a stronger base is required (e.g., phenyllithium or sodium amide). The R and R′ groups, may be alkyl,[406] aryl, or vinylic.[407] Also, one of the hydrogens may be replaced by an alkyl or aryl group, in which case the product is the salt of a tertiary alcohol. Migratory aptitudes



[399]For example, see Buston, J.E.H.; Coldham, I.; Mulholland, K.R. *Tetrahedron Asymmetry*, ***1998***, *9*, 1995.
[400]Migration of aryl and of certain alkyl groups has also been reported. See Khuthier, A.; Al-Mallah, K.Y.; Hanna, S.Y.; Abdulla, N.I. *J. Org. Chem.* ***1987***, *52*, 1710, and references cited therein.

[407]For migration of vinyl, see Rautenstrauch, V.; Büchi, G.; Wüest, H. *J. Am. Chem. Soc.* ***1974***, *96*, 2576. For rearrangment of an α-trimethylsilyl allyl ether, see Maleczka, Jr., R.E.; Geng, F. *Org. Lett.* ***1999***, *1*, 1115.

here are allylic, benzylic > ethyl > methyl > phenyl.[408] The stereospecificity of the 1,2-Wittig rearrangement has been discussed.[409] The following radical-pair mechanism[410] (similar to mechanism *a* of **18-21**) is likely, after removal of the proton by the base. One of the radicals in the radical pair is a ketyl. Among the evidence for this mechanism is (*1*) the rearrangement is largely intramolecular; (*2*) migratory aptitudes are in the order of free-radical stabilities, not of carbanion stabilities[411] (which rules out an ion-pair mechanism similar to mechanism *b* of **18-21**); (*3*) aldehydes are obtained as side products;[412] (*4*) partial racemization of R' has been observed[413] (the remainder of the product retained its configuration); (*5*) crossover products have been detected;[414] and (*6*) when ketyl radicals and R radicals from different precursors were brought together, similar products resulted.[415] However, there is evidence that at least in some cases the radical-pair mechanism accounts for only a portion of the product, and some kind of concerted mechanism can also take place.[416] Most of the above investigations were carried out with systems where R' is alkyl, but a radical-pair mechanism has also been suggested for the case where R' is aryl.[417] When R' is allylic a concerted mechanism can operate (**18-35**).

When R is vinylic it is possible, by using a combination of an alkyllithium and *t*-BuOK, to get migration to the γ carbon (as well as to the α carbon), producing an enolate that, on hydrolysis, gives an aldehyde:[418]

$$CH_2{=}CH{-}CH_2{-}OR' \longrightarrow R'CH_2{-}CH{=}CH{-}OLi \longrightarrow R'CH_2CH_2CHO$$

An aza-Wittig rearrangement is also known.[419]

There are no OS references, but see OS **VIII**, 501, for a related reaction.

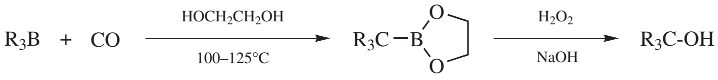
F. Boron-to-Carbon Migrations[420]

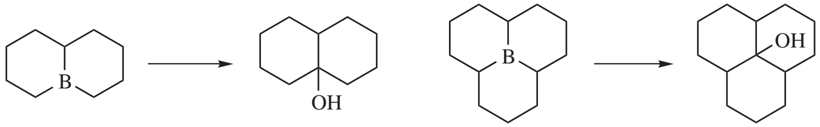
For another reaction involving boron-to-carbon migration, see **10-73**.

18-23 Conversion of Boranes to Alcohols



86

Trialkylboranes (which can be prepared from alkenes by **15-16**) react with carbon monoxide[421] at 100–125°C in the presence of ethylene glycol to give the 2-bora-1,3-dioxolanes (**86**), which are easily oxidized (**12-27**) to tertiary alcohols.[422] The R groups may be primary, secondary, or tertiary, and may be the same or different.[423] Yields are high and the reaction is quite useful, especially for the preparation of sterically hindered alcohols, such as tricyclohexylcarbinol (**87**) and tri-2-norbornylcarbinol (**88**), which are difficult to prepare by **16-24**. Heterocycles in which boron is a ring atom react similarly (except that high CO pressures are required), and cyclic alcohols can be obtained from these substrates.[424] The preparation of such heterocyclic boranes was discussed at **15-16**. The overall conversion of a diene or triene to a cyclic alcohol has been described by H.C. Brown as "stitching" with boron and "riveting" with carbon.



87 **88**

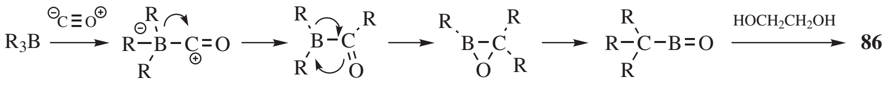
Though the mechanism has not been investigated thoroughly, it has been shown to be intramolecular by the failure to find crossover products when mixtures of boranes are used.[425] The following scheme, involving three boron-to-carbon migrations, has been suggested.



89 **90**

The purpose of the ethylene glycol is to intercept the boronic anhydride **90**, which otherwise forms polymers that are difficult to oxidize. As we will see in **18-23** and **18-24**, it is possible to stop the reaction after only one or two migrations have taken place.

Method 1 $$R_3B + CHCl_2OMe \xrightarrow[\text{2. } H_2O_2\text{—NaOH}]{\text{1. LiOCEt}_3\text{—THF}} R_3COH$$

Method 2 $$R_3B + {}^{\ominus}CN \xrightarrow{\text{THF}} \underset{\mathbf{91}}{R_3\overset{\ominus}{B}\text{—}CN} \xrightarrow[\text{2. NaOH—}H_2O_2]{\text{1. excess }(CF_3CO)_2O} R_3COH$$

There are two other methods for achieving the conversion $R_3B \rightarrow R_3COH$, which often give better results: (*1*) treatment with α,α-dichloromethyl methyl ether and the base lithium triethylcarboxide[426] (*2*) treatment with a suspension of sodium cyanide in THF followed by reaction of the resulting trialkylcyanoborate **91** with an excess (>2 equivalents) of trifluoroacetic anhydride.[427] All the above migrations take place with retention of configuration at the migrating carbon.[428]

Several other methods for the conversion of boranes to tertiary alcohols are also known.[429]

If the reaction between trialkylboranes and carbon monoxide (**18-23**) is carried out in the presence of water followed by addition of NaOH, the product is a secondary alcohol. If H_2O_2 is added along with the NaOH, the corresponding ketone is obtained instead.[430] Various functional groups (e.g., OAc, COOR, CN) may be

present in R without being affected,[431] though if they are in the α or β position relative to the boron atom, difficulties may

$$\overset{\ominus}{R_3B{-}CN} \xrightarrow[\text{2. } H_2O_2{-}OH^-]{\text{1. } (CF_3CO)_2O} RCOR$$

91

be encountered. The use of an equimolar amount of trifluoroacetic anhydride leads to the ketone rather than the tertiary alcohol.[427,432] By this procedure, thexylboranes (RR'R^2B, where R^2 = thexyl) can be converted to unsymmetrical ketones (RCOR').[433] Variations of this methodology have been used to prepare optically active alcohols.[434]

For another conversion of trialkylboranes to ketones (see **18-26**).[435] Other conversions of boranes to secondary alcohols are also known.[436]

OS **VII**, 427. Also see, OS **VI**, 137.

18-24 Conversion of Boranes to Primary Alcohols, Aldehydes, or Carboxylic Acids

$$R_3B + CO \xrightarrow[\text{2. } H_2O_2\text{-}OH^-]{\text{1. } LiBH_4} RCH_2OH$$

$$R_3B + CO \xrightarrow[\text{2. } H_2O_2\text{-}NaH_2PO_4\text{-}Na_2HPO_4]{\text{1. } LiAlH(OMe)_3} RCHO$$

When the reaction between a trialkylborane and carbon monoxide (**18-23**) is carried out in the presence of a reducing agent such as lithium borohydride or potassium triisopropoxyborohydride, the reduction agent intercepts the intermediate **89**, so that only one boron-to-carbon migration takes place, and the product is hydrolyzed to a primary alcohol or oxidized to an aldehyde.[437] This procedure wastes two of the three R groups, but this problem can be avoided by the use of

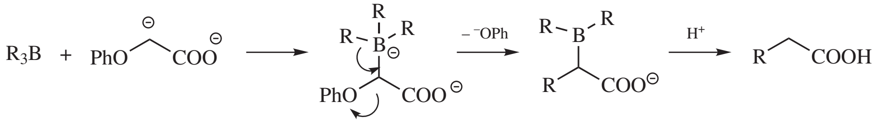
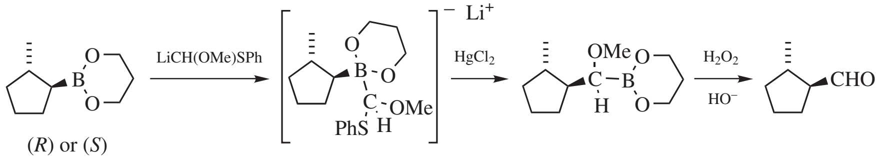
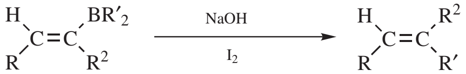
B-alkyl-9-BBN derivatives (p. 1077). Since only the 9-alkyl group migrates, this method permits the conversion in high yield of an alkene to a primary alcohol or aldehyde containing one more carbon.[438] When B-alkyl-9-BBN derivatives are treated with CO and lithium tri-*tert*-butoxyaluminum hydride,[439] other functional groups (e.g., CN and ester) can be present in the alkyl group without being reduced.[440] Boranes can be directly converted to carboxylic acids by reaction with the dianion of phenoxyacetic acid.[441]



Boronic esters $RB(OR')_2$ react with methoxy(phenylthio)methyllithium LiCH(OMe)SPh to give salts, which, after treatment with $HgCl_2$, and then H_2O_2, yield aldehydes.[442] This synthesis has been made enantioselective, with high ee values (>99%), by the use of an optically pure boronic ester,[443] for example:



18-25 Conversion of Vinylic Boranes to Alkenes



The reaction between trialkylboranes and iodine to give alkyl iodides was mentioned at **12-31**. When the substrate contains a vinylic group, the reaction takes a different course,[444] with one of the R' groups migrating to the carbon, to give alkenes.[445] The reaction is stereospecific in two senses: (*1*) if the groups

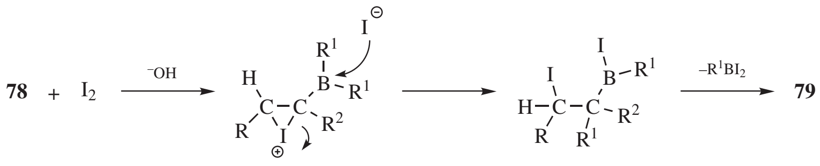
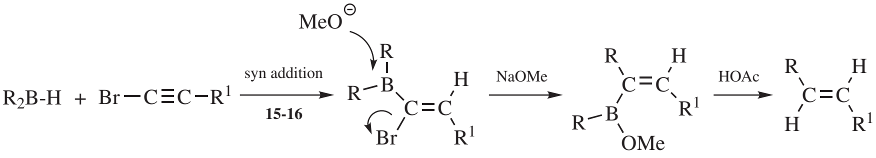
R and R″ are cis in the starting compound, they will be trans in the product; (*2*) there is retention of configuration within the migrating group R′.[446] Since vinylic boranes can be prepared from alkynes (**15-16**), this is a method for the addition of R′ and H to a triple bond. If $R^2 = H$, the product is a (*Z*)-alkene. The mechanism is believed to involve an iodonium intermediate, such as **92**, and attack by iodide on boron. When R′ is vinylic, the product is a conjugated diene.[447]



92

In another procedure, the addition of a dialkylborane to a 1-haloalkyne produces an α-halo vinylic borane (**93**).[448] Treatment of this with NaOMe gives the rearrangement shown, and protonolysis of the product



93

produces the (*E*)-alkene.[446] If R is a vinylic group the product is a 1,3-diene.[449] If one of the groups is thexyl, the other migrates.[450] This extends the scope of the synthesis, since dialkylboranes where one R group is thexyl are easily prepared. A combination of both of the procedures described above results in the preparation of trisubstituted alkenes.[451] The entire conversion of haloalkyne to alkene can be carried out in one reaction vessel, without isolation of intermediates. An aluminum counterpart of the α-halo vinylic borane procedure has been reported.[452]

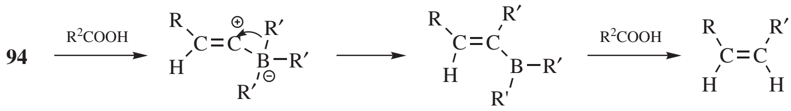
18-26 Formation of Alkynes, Alkenes, and Ketones from Boranes and Acetylides

94

A hydrogen directly attached to a triple-bond carbon can be replaced in high yield by an alkyl or an aryl group, by treatment of the lithium acetylide with a trialkyl- or triarylborane, followed by reaction of the lithium alkynyltrialkylborate **94** with iodine.[453] The R′ group may be primary or secondary alkyl as well as aryl, so the reaction has a broader scope than the older reaction **10-74**.[454] The R group may be alkyl, aryl, or hydrogen, though in the last-mentioned case satisfactory yields are obtained only if lithium acetylide–ethylenediamine is used as the starting



compound.[455] Optically active alkynes can be prepared by using optically active thexylborinates (RR^{2}BOR', R^2 = thexyl), where R is chiral, and LiC≡CSiMe$_3$.[456] The reaction can be adapted to the preparation of alkenes[414] by treatment of **94** with an electrophile such as propanoic acid[457] or tributyltin chloride.[458] The reaction with Bu$_3$SnCl produces the (*Z*)-alkene stereoselectively.

Treatment of **94** with an electrophile, such as methyl sulfate, allyl bromide, or triethyloxonium borofluoride, followed by oxidation of the resulting vinylic borane gives a ketone (illustrated for methyl sulfate):[459]

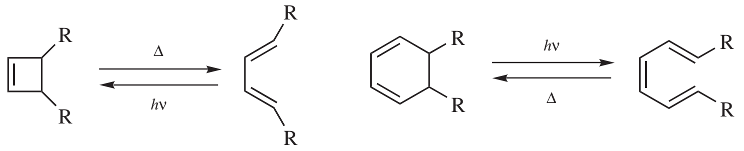
NON-1,2 REARRANGEMENTS

A. Electrocyclic Rearrangements

18-27 Electrocyclic Rearrangements of Cyclobutenes and 1,3-Cyclohexadienes

(4)*seco*-1/4/Detachment; (4)*cyclo*-1/4/Attachment
(6)*seco*-1,6/Detachment; (6)*cyclo*-1/6/Attachment



Cyclobutenes and 1,3-dienes can be interconverted by treatment with uv light or with heat.[461] The thermal reaction is generally not reversible (although exceptions[462] are known), and many cyclobutenes have been converted to 1,3-dienes by heating at temperatures between 100 and 200°C. The photochemical conversion can in principle be carried out in either direction, but most often 1,3-dienes are converted to cyclobutenes rather than the reverse, because the dienes are stronger absorbers of light at the wavelengths used.[463] In a similar reaction, 1,3-cyclohexadienes interconvert with 1,3,5-trienes, but in this case the ring-closing process is generally favored thermally and the ring-opening process photochemically, though exceptions are known in both directions.[464] Substituent effects can lead to acceleration of the electrocyclization process.[465] Torquoselectivity in cyclobutene ring opening reaction has been examined.[466]

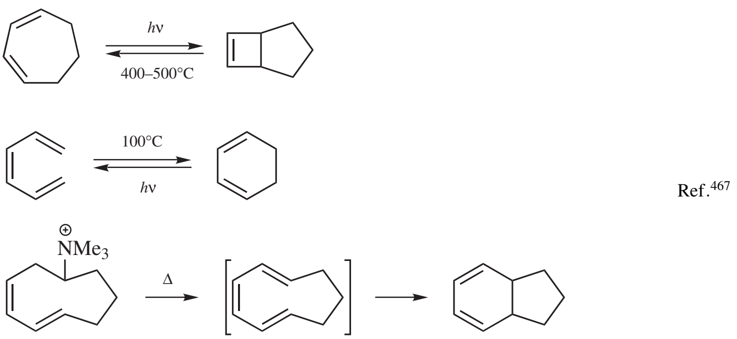
Some examples are



An interesting example of 1,3-cyclohexadiene–1,3,5-triene interconversion is the reaction of norcaradienes to give cycloheptatrienes.[468] Norcaradienes give this reaction so readily (because they are *cis*-1,2-divinylcyclopropanes, see p. 1661) that they cannot generally be isolated, though some exceptions are known[469,470] (see also, p. 1239).

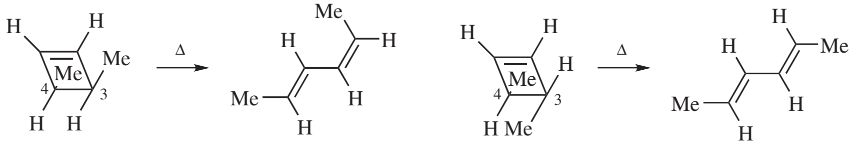
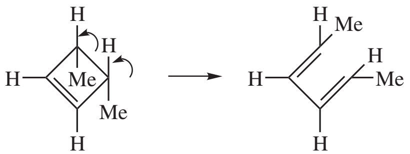
These reactions, called *electrocyclic rearrangements*,[471] take place by pericyclic mechanisms. The evidence comes from stereochemical studies, which show a remarkable stereospecificity whose direction depends on whether the reaction is induced by heat or light. For example, it was found for the thermal reaction that *cis*-3,4-dimethylcyclobutene gave only *cis*,*trans*-2,4-hexadiene, while the trans isomer gave only the trans–trans diene:[472]



This is evidence for a four-membered cyclic transition state and arises from conrotatory motion about the C-3–C-4 bond.[473] It is called conrotatory because both movements are clockwise (or both counterclockwise). Because both rotate in the same direction, the cis isomer gives the cis–trans diene:[474]



The other possibility (*disrotatory* motion) would have one moving clockwise while the other moves counterclockwise; the cis isomer would have given the cis–cis

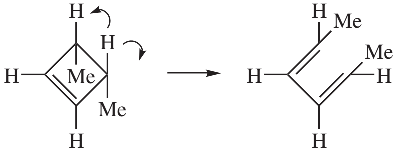
[473]The mechanism of cyclobutene thermal isomerization has been examined. See Baldwin, J.E.; Gallagher, S.S.; Leber, P.A.; Raghavan, A.S.; Shukla, R. *J. Org. Chem.* ***2004***, *69*, 7212.

[474]This picture is from Woodward, R.B.; Hoffmann, R. *J. Am. Chem. Soc.* ***1965***, *87*, 395, who coined the terms, *conrotatory* and *disrotatory*.

diene (shown) or the trans–trans diene:



If the motion had been disrotatory, this would still have been evidence for a cyclic mechanism. If the mechanism were a diradical or some other kind of noncyclic process, it is likely that no stereospecificity of either kind would have been observed. The reverse reaction is also conrotatory. In contrast, the photochemical cyclobutene: 1,3-Diene interconversion is *disrotatory* in either direction.[475] On the other hand, the cyclohexadiene: 1,3,5-Triene interconversion shows precisely the opposite behavior. The thermal process is *disrotatory*, while the photochemical process is *conrotatory* (in either direction). These startling results are a consequence of the symmetry rules mentioned in Chapter 15 (p. 1208).[476] As in the case of cycloaddition reactions, we will use the frontier orbital and Möbius–Hückel approaches.[477]

The Frontier Orbital Method[478]

As applied to these reactions, the frontier orbital method may be expressed: *A σ bond will open in such a way that the resulting p orbitals will have the symmetry of the highest occupied π orbital of the product.* In the case of cyclobutenes, the HOMO of the product in the thermal reaction is the χ_2 orbital (Fig. 18.1).

[475]Photochemical ring opening of cyclobutenes can also be nonstereospecific. See Leigh, W.J.; Zheng, K. *J. Am. Chem. Soc.* ***1991***, *113*, 4019; Leigh, W.J.; Zheng, K.; Nguyen, N.; Werstiuk, N.H.; Ma, J. *J. Am. Chem. Soc.* ***1991***, *113*, 4993, and references cited therein.

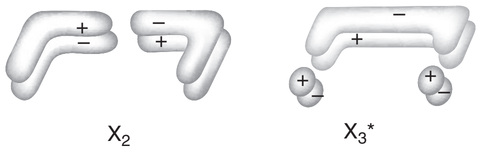

Fig. 18.1. Symmetries of the X_2 and X_3* orbitals of a conjugated diene.

Therefore, in a thermal process, the cyclobutene must open so that on one side the positive lobe lies above the plane, and on the other side below it. Thus the substituents are forced into conrotatory motion (Fig. 18.2). On the other hand, in the photochemical process, the HOMO of the product is now the χ_3 orbital (Fig. 18.1), and in order for the *p* orbitals to achieve this symmetry (the two plus lobes on the same side of the plane), the substituents are forced into disrotatory motion.

We may also look at this reaction from the opposite direction (ring closing). For this direction, the rule is that *those lobes of orbitals that overlap (in the HOMO) must be of the same sign*. For thermal cyclization of butadienes, this requires conrotatory motion (Fig. 18.3). In the photochemical process the HOMO is the χ_3 orbital, so that disrotatory motion is required for lobes of the same sign to overlap.

The Möbius–Hückel Method[481]

As we saw on p. 1210, in this method we choose a basis set of *p* orbitals and look for sign inversions in the transition state. Figure 18.4 shows a basis set for a 1,3-diene. It is seen that disrotatory ring closing (Fig. 18.4*a*) results in overlap of plus lobes only, while in conrotatory closing (Fig. 18.4*b*) there is one overlap of a plus

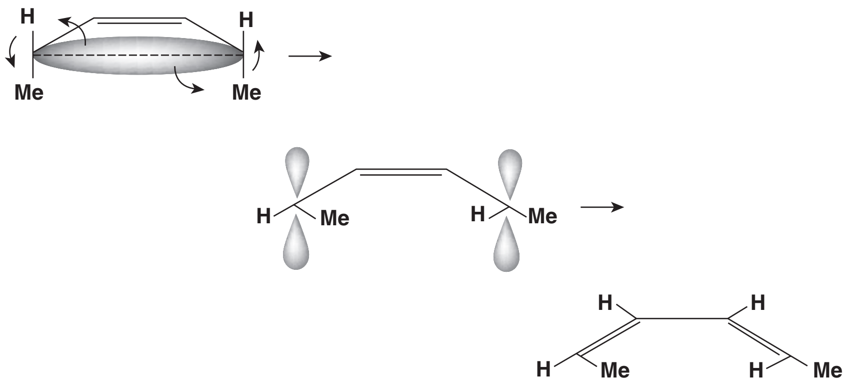

Fig. 18.2. Thermal opening of 1,2-dimethylcyclobutene. The two hydrogens and two methyls are forced into conrotatory motion so that the resulting *p* orbitals have the symmetry of the HOMO of the diene.

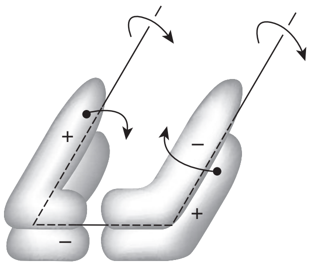

Fig. 18.3. Thermal ring closing of a 1,3-diene. Conrotatory motion is required for two + lobes to overlap.

with a minus lobe. In the first case, we have zero sign inversions, while in the second there is one sign inversion. With zero (or an even number of) sign inversions, the disrotatory transition state is a Hückel system, and so is allowed thermally only if the total number of electrons is $4n + 2$ (p. 1211). Since the total here is 4, the

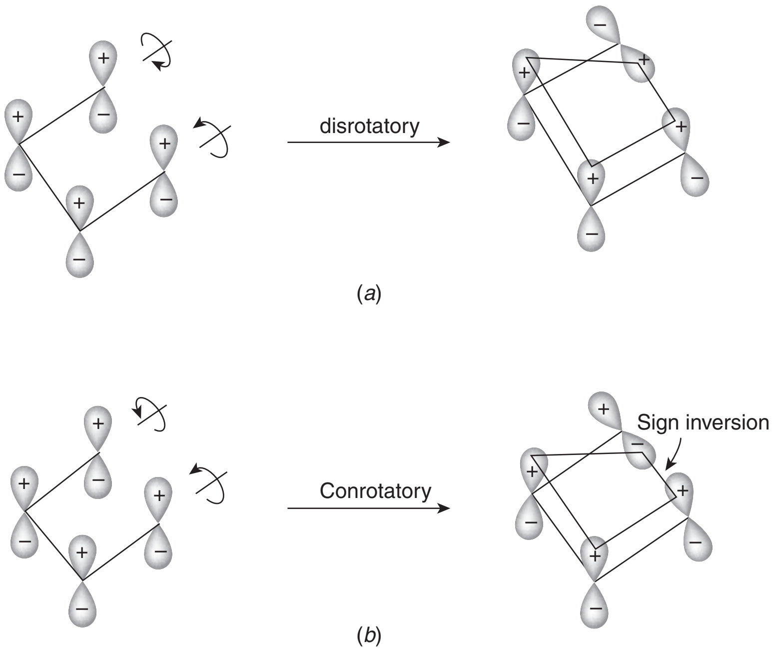

Fig. 18.4. The 1,3-diene–cyclobutene interconversion. The orbitals shown are *not* molecular orbitals, but a basis set of *p*-atomic orbitals. (*a*) Disrotatory ring closure gives zero sign inversion. (*b*) Conrotatory ring closure gives one sign inversion. We could have chosen to show any other basis set (e.g., another basis set would have two plus lobes above the plane and two below, etc.). This would change the number of sign inversion, but the disrotatory mode would still have an even number of sign inversions, and the conrotatory mode an odd number, whichever basis set was chosen.

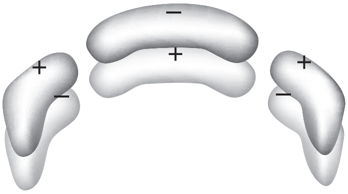
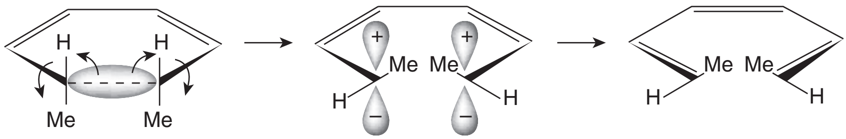
disrotatory process is not allowed. On the other hand, the conrotatory process, with one sign inversion, is a Möbius system, which is thermally allowed if the total number is $4n$. The conrotatory process is therefore allowed thermally. For the photochemical reactions, the rules are reversed: A reaction with $4n$ electrons requires a Hückel system, so only the disrotatory process is allowed.

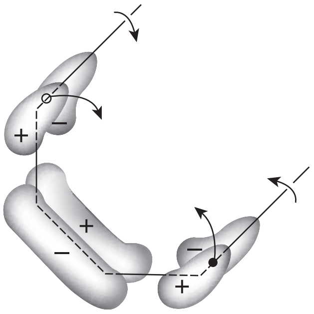
Both the frontier orbital and the Möbius–Hückel methods can also be applied to the cyclohexadiene: 1,3,5-triene reaction;[479] in either case the predicted result is that for the thermal process, only the disrotatory pathway is allowed, and for the photochemical process, only the conrotatory. For example, for a 1,3,5-triene, the symmetry of the HOMO is



In the thermal cleavage of cyclohexadienes, then, the positive lobes must lie on the same side of the plane, requiring disrotatory motion:



Disrotatory motion is also necessary for the reverse reaction, in order that the orbitals that overlap may be of the same sign:

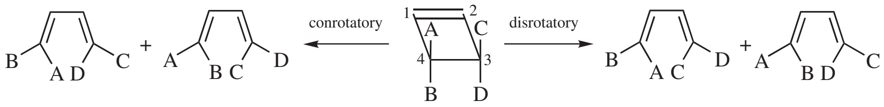


[479]For a discussion of the transition structures and energy, see Zora, M. *J. Org. Chem.* ***2004***, *69*, 1940.

All these directions are reversed for photochemical processes, because in each case a higher orbital, with inverted symmetry, is occupied.

In the Möbius–Hückel approach, diagrams similar to Fig. 18.4 can be drawn for this case. Here too, the disrotatory pathway is a Hückel system and the conrotatory pathway a Möbius system, but since six electrons are now involved, the thermal reaction follows the Hückel pathway and the photochemical reaction the Möbius pathway.

In the most general case, there are four possible products that can arise from a given cyclobutene or cyclohexadiene: two from the conrotatory and two from the disrotatory pathway. For example, conrotatory ring opening of **95** gives either **96** or **97**, while disrotatory opening gives either **98** or **99**. The orbital-symmetry rules tell us when a given reaction will operate by the conrotatory and when by the disrotatory mode, but they do not say which of the two possible conrotatory or disrotatory pathways will be followed. It is often possible,



96 **97** **95** **98** **99**

however, to make such predictions on steric grounds. For example, in the opening of **95** by the disrotatory pathway, **98** arises when groups A and C swing in toward each other (clockwise motion around C-4, counterclockwise around C-3), while **99** is formed when groups B and D swing in and A and C swing out (clockwise motion around C-3, counterclockwise around C-4). We therefore predict that when A and C are larger than B and D, the predominant or exclusive product will be **99**, rather than **98**. Predictions of this kind have largely been borne out.[480] There is evidence, however, that steric effects[481] are not the only factor, and that electronic effects also play a role, which may be even greater.[482] An electron-donating group stabilizes the transition state when it rotates *outward*, because it mixes with the LUMO; if it rotates *inward*, it mixes with the HOMO, destabilizing the transition state.[483] The compound 3-formylcyclobutene provided a test. Steric factors would cause the CHO

[480]For example, see Baldwin, J.E.; Krueger, S.M. *J. Am. Chem. Soc.* ***1969***, *91*, 6444; Spangler, C.W.; Hennis, R.P. *J. Chem. Soc., Chem. Commun.* ***1972***, 24; Gesche, P.; Klinger, F.; Riesen, A.; Tschamber, T.; Zehnder, M.; Streith, J. *Helv. Chim. Acta* ***1987***, *70*, 2087.

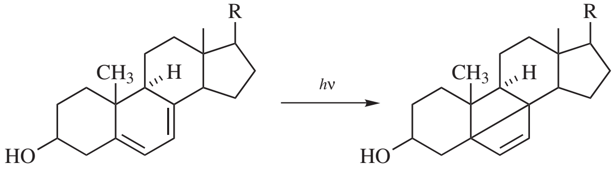
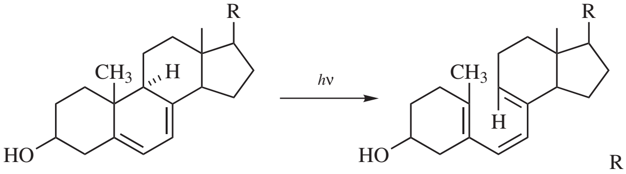
(an electron-withdrawing group) to rotate outward; electronic effects would cause it to rotate inward. The experiment showed inward rotation.[484]



100



101 **102**

R = C_9H_{17}

Cyclohexadienes are of course 1,3-dienes, and in certain cases it is possible to convert them to cyclobutenes instead of to 1,3,5-trienes.[485] An interesting example is found in the pyrocalciferols. Photolysis of the syn isomer **100** (or of the other syn isomer, not shown) leads to the corresponding cyclobutene,[486] while photolysis of the anti isomers (one of them is **101**) gives the ring-opened 1,3,5-triene, **102**. This difference in behavior is at first sight remarkable, but is easily explained by the orbital-symmetry rules. Photochemical ring opening to a 1,3,5-triene must be conrotatory. If **100** were to react by this pathway, the product would be the triene **102**, but this compound would have to contain a *trans*-cyclohexene ring (either the methyl group or the hydrogen would have to be directed inside the ring). On the other hand, photochemical conversion to a cyclobutene must be disrotatory, but if **101** were to give this reaction, the product would have to have a trans-fused ring junction. Compounds with such ring junctions are known (p. 188), but are very strained. Stable *trans*-cyclohexenes are unknown (p. 226). Thus, **100** and **101** give the products they do owing to a combination of orbital-symmetry rules and steric influences.

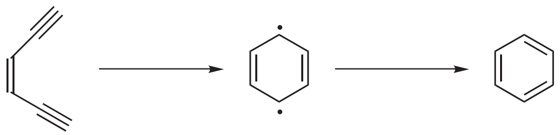
[485]For a discussion of the factors favoring either direction, see Dauben, W.G.; Kellogg, M.S.; Seeman, J.I.; Vietmeyer, N.D.; Wendschuh, P.H. *Pure Appl. Chem.* ***1973***, *33*, 197.

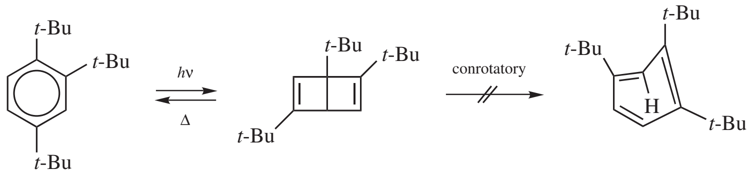
[486]Dauben, W.G.; Fonken, G.J. *J. Am. Chem. Soc.* ***1959***, *81*, 4060. This was the first reported example of the conversion of a 1,3-diene to a cyclobutene.

A variation of this process is the *Bergmann cyclization*,[487] where an ene-diyne cyclizes to a biradical (**103**) and then aromatizes as shown.



103

Simply heating the en-diyne will usually lead to aromatization via this pathway.[488] Quinones can be formed via Bergman cyclization[489] and there are other synthetic applications.[490] The role of vinyl substitution has been examined.[491] An aza-Bergman cyclization is known.[492]



104 **105** **106**

The 1,3-diene-cyclobutene interconversion can even be applied to benzene rings. For example,[493] photolysis of 1,2,4-tri-*tert*-butylbenzene (**104**) gives

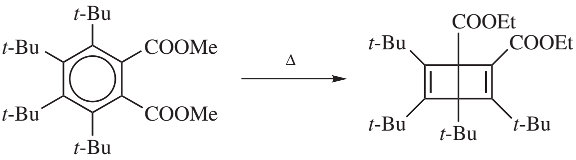
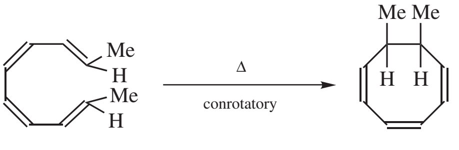
[493]Unsubstituted Dewar benzene has been obtained, along with other photoproducts, by photolysis of benzene: Ward, H.R.; Wishnok, J.S. *J. Am. Chem. Soc.* ***1968***, *90*, 1085; Bryce-Smith, D.; Gilbert, A.; Robinson, D.A. *Angew. Chem. Int. Ed.* ***1971***, *10*, 745. For other examples, see Arnett, E.M.; Bollinger, J.M. *Tetrahedron Lett.* ***1964***, 3803; Camaggi, G.; Gozzo, F.; Cevidalli, G. *Chem. Commun.* ***1966***, 313; Haller, I. *J. Am. Chem. Soc.* ***1966***, *88*, 2070; *J. Chem. Phys.* ***1967***, *47*, 1117; Barlow, M.G.; Haszeldine, R.N.; Hubbard, R. *Chem. Commun.* ***1969***, 202; Lemal, D.M.; Staros, J.V.; Austel, V. *J. Am. Chem. Soc.* ***1969***, *91*, 3373.

1,2,5-tri-*tert*-butyl[2.2.0]hexadiene (**105**, a Dewar benzene).[494] The reaction owes its success to the fact that once **105** is formed, it cannot, under the conditions used, revert to **104** by either a thermal or a photochemical route. The orbital-symmetry rules prohibit thermal conversion of **105** to **104** by a pericyclic mechanism, because thermal conversion of a cyclobutene to a 1,3-diene must be conrotatory, and conrotatory reaction of **105** would result in a 1,3,5-cyclohexatriene containing one trans double bond (**106**), which is of course too strained to exist. Compound **105** cannot revert to **104** by a photochemical pathway either, because light of the frequency used to excite **104** would not be absorbed by **105**. This is thus another example of a molecule that owes its stability to the orbital-symmetry rules (see p. 1232). Pyrolysis of **105** does give **104** , probably by a diradical mechanism.[495] In the case of **107** and **108**, the Dewar benzene is actually more stable than the benzene. Compound **107** rearranges to **108** in 90% yield at 120°C.[496] In this case, thermolysis of the benzene gives the Dewar benzene (rather than the reverse), because of the strain of four adjacent *tert*-butyl groups on the ring.



107 **108**

A number of electrocyclic reactions have been carried out with systems of other sizes, for example, conversion of the 1,3,5,7-octatetraene **109** to the cyclooctatriene **110**.[497] The stereochemistry of these reactions can be predicted in a



109 **110**

[494]Wilzbach, K.E.; Kaplan, L. *J. Am. Chem. Soc.* ***1965***, *87*, 4004; van Tamelen, E.E.; Pappas, S.P.; Kirk, K.L. *J. Am. Chem. Soc.* ***1971***, *93*, 6092; van Tamelen, E.E. *Acc. Chem. similar manner. The results of such predictions can be summarized according to whether the number of electrons involved in the cyclic process is of the form 4*n* or 4*n* + 2 (where *n* is any integer including zero).

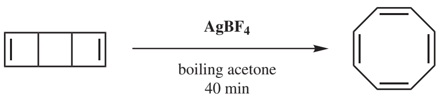
	Thermal Reaction	Photochemical Reaction
4*n*	Conrotatory	Disrotatory
4*n* + 2	Disrotatory	Conrotatory

Although the orbital-symmetry rules predict the stereochemical results in almost all cases, it is necessary to recall (p. 1210) that they only say what is allowed and what is forbidden, but the fact that a reaction is allowed does not necessarily mean that the reaction takes place, and if an allowed reaction does take place, it does not *necessarily* follow that a concerted pathway is involved, since other pathways of lower energy may be available.[498] Furthermore, a "forbidden" reaction might still be made to go, if a method of achieving its high activation energy can be found. This was, in fact, done for the cyclobutene butadiene interconversion (*cis*-3,4-dichlorocyclobutene gave the forbidden *cis*,-*cis*- and *trans*,*trans*-1,4-dichloro-1,3-butadienes, as well as the allowed cis, trans isomer) by the use of ir laser light.[499] This is a thermal reaction. The laser light excites the molecule to a higher vibrational level (p. 330), but not to a higher electronic state.

As is the case for [2+2]-cycloaddition reactions (**15-63**), certain forbidden electrocyclic reactions can be made to take place by the use of metallic catalysts.[500] An example is the silver ion-catalyzed conversion of tricyclo[4.2.0.0^{2,5}]octa-3,7-diene to cyclooctatetraene:[501]



This conversion is very slow thermally (i.e., without the catalyst) because the reaction must take place by a disrotatory pathway, which is disallowed thermally.[502] In another example, the major thermal product from the barrelene anion is a

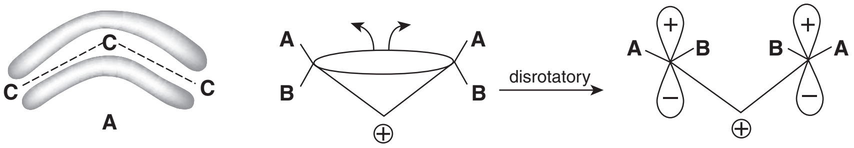
rearranged allyl anion that is formed by disrotatory cleavage of the cyclopropyl ring, a formally Woodward–Hoffmann-forbidden process.[503]

The ring opening of cyclopropyl cations (pp. 486, 1591) is an electrocyclic reaction and is governed by the orbital symmetry rules.[504] For this case, we invoke the rule that the *s* bond opens in such a way that the resulting *p* orbitals have the symmetry of the highest occupied orbital of the product, in this case, an allylic cation. We may recall that an allylic system has three molecular orbitals (p. 42). For the cation, with only two electrons, the highest occupied orbital is the one of the lowest energy (A). Thus, the cyclopropyl cation must undergo a



disrotatory ring opening in order to maintain the symmetry. (Note that, in contrast, ring opening of the cyclopropyl *anion* must be conrotatory,[505] since in this case it is the next orbital of the allylic system that is the highest occupied, and this has the opposite symmetry.[506]) However, it is very difficult to generate a free cyclopropyl cation (p. 487), and it is likely that in most cases, cleavage of the σ bond is concerted with departure of the leaving group in the original cyclopropyl substrate. This, of course, means that the σ bond provides anchimeric assistance to the removal of the leaving group (an S_N2-type process), and we would expect that such assistance should come from the back side. This has an important effect on the direction of ring opening. The orbital-symmetry rules require that the ring opening be disrotatory, but as we have seen, there are two disrotatory pathways and the rules do not tell us which is preferred. But the fact that the *s* orbital provides assistance from the backside means that the two substituents that are trans to the leaving group must move *outward*, not inward.[507] Thus, the disrotatory pathway that is followed is the one shown in B, not the one shown in C, because the former puts the electrons of the σ bond on the

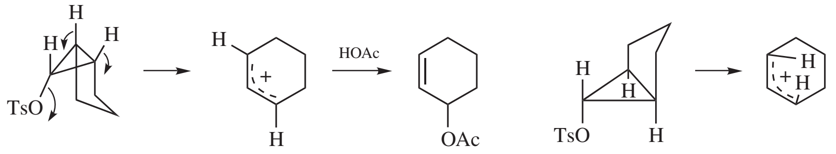
[505]For a review of ring opening of cyclopropyl anions and related reactions, see Boche, G. *Top. Curr. Chem.* ***1988***, *146*, 1.

[506]For evidence that this is so, see Newcomb, M.; Ford, W.T. *J. Am. Chem. Soc.* ***1974***, *96*, 2968; Boche, G.; Buckl, K.; Martens, D.; Schneider, D.R.; Wagner, H. *Chem. Ber.* ***1979***, *112*, 2961; Coates, R.M.; Last, L.A. *J. Am. Chem. Soc.* ***1983***, *105*, 7322. For a review of the analogous ring opening of epoxides, see Huisgen, R. *Angew. Chem. Int. Ed.* ***1977***, *16*, 572.

[507]This was first proposed by DePuy, C.H.; Schnack, L.G.; Hausser, J.W.; Wiedemann, W. *J. Am. Chem. Soc.* ***1965***, *87*, 4006.

side opposite that of the leaving group.[508] Strong confirmation of this picture[509] comes from acetolysis of *endo*- (**111**) and *exo*-bicyclo[3,1,0]hexyl-6-tosylate (**112**). The groups trans to the tosylate must move outward. For **111**, this means that the two hydrogens can go outside the framework of the six-membered ring, but for **112** they



111 **112**

are forced to go inside. Consequently, it is not surprising that the rate ratio for solvolysis of **111/112** was found to be >2.5 × 10^6 and that at 150°C **112** did not solvolyze at all.[510] This evidence is kinetic. Unlike the cases of the cyclobutene (1,3-diene and cyclohexadiene) 1,3,5-triene interconversions, the direct product here is a cation, which is not stable but reacts with a nucleophile and loses some of its steric integrity in the process, so that much of the evidence has been of the kinetic type rather than from studies of product stereochemistry. However, it has been shown by investigations in superacids, where it is possible to keep the cations intact and to study their structures by NMR, that in all cases studied the cation that is predicted by these rules is in fact formed.[511]

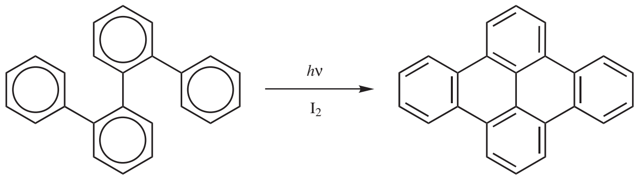
Pd–C,[513] or iodine.[514] The reaction is a photochemically allowed conrotatory[515] conversion of a 1,3,5-hexatriene to a cyclohexadiene, followed by removal of two hydrogen atoms by the oxidizing agent. The intermediate dihydrophenanthrene has been isolated.[516] The use of substrates containing heteroatoms (e.g., PhN=NPh) allows the formation of heterocyclic ring systems. The actual reacting species must be the *cis*-stilbene, but *trans*-stilbenes can often be used, because they are isomerized to the cis isomers under the reaction conditions. The reaction can be extended to the preparation of many fused aromatic systems, for example,[517]



though not all such systems give reaction.[518]

Isomerization of biphenylene to benzo[*a*]pentalene[519] is a well-known benzene ring contraction rearrangement,[520] driven by relief of strain in the four-membered ring. Related to this process is the FVP of the alternant polycyclic aromatic hydrocarbon benzo[*b*]biphenylene at 1100°C, which gives fluoranthene, a nonalternant polycyclic aromatic hydrocarbon, as the major product at 1100°C in the gas phase.[521] The mechanism used explain that this isomerization involves equilibrating diradicals of 2-phenylnaphthalene, which rearrange by the net migration of a phenyl group to give equilibrating diradicals of 1-phenylnaphthalene, one isomer of which then cyclizes to fluoranthene.

Another transformation of one aromatic compound to another is the *Stone–Wales rearrangement* of pyracyclene (**113**),[522] which is a bond-switching reaction. The rearrangement of bifluorenylidene (**114**) to dibenzo[*g,p*]chrysene (**115**) occurs at temperatures as low as 400°C and is accelerated in the presence of decomposing iodomethane, a convenient source of methyl radicals.[523] This result suggested a

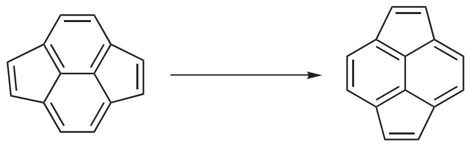
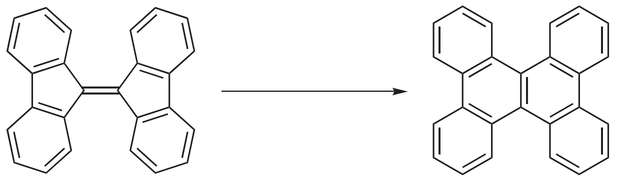
radical rearrangement. This rearrangement is believed to occur by a radical-promoted mechanism consisting of a sequence of homoallyl–cyclopropylcarbinyl rearrangement steps.[524]



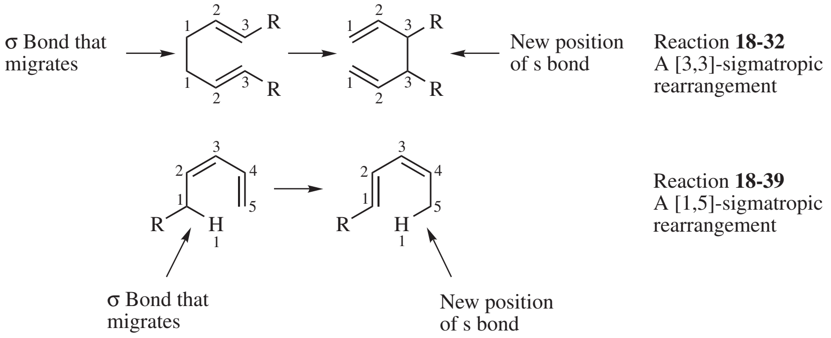
113



114 **115**

B. Sigmatropic Rearrangements

A sigmatropic rearrangement is defined[525] as migration, in an uncatalyzed intramolecular process, of a σ bond, adjacent to one or more π systems, to a new position in a molecule, with the π systems becoming reorganized in the process. Examples are



The *order* of a sigmatropic rearrangement is expressed by two numbers set in brackets: [*i*,*j*]. These numbers can be determined by counting the atoms over which each end of the σ bond has moved. Each of the original termini is given the number 1. Thus in the first example above, each terminus of the σ bond has

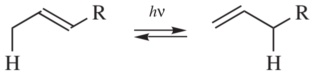
[524]Alder, R.W.; Harvey, J. N. *J. Am. Chem. Soc.* ***2004***, *126*, 2490.

[525]Woodward, R.B.; Hoffmann, R. *The Conservation of Orbital Symmetry*, Academic Press, NY, ***1970***, p. 114.

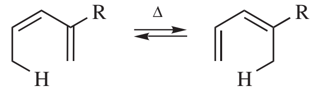
migrated from C-1 to C-3, so the order is [3,3]. In the second example, the carbon terminus has moved from C-1 to C-5, but the hydrogen terminus has not moved at all, so the order is [1,5].

18-29 [1,*j*]-Sigmatropic Migrations of Hydrogen

1/ → 3/Hydrogen-migration; 1/ → 5/Hydrogen-migration



[1,3]



[1,5]

Many examples of thermal or photochemical rearrangements in which a hydrogen atom migrates from one end of a system of π bonds to the other have been reported,[526] although the reaction is subject to geometrical conditions. Isotope effects play a role in sigmatropic rearrangements, and there is evidence for a kinetic silicon isotope effect.[527] Pericyclic mechanisms are involved,[528] and the hydrogen must, in the transition state, be in contact with both ends of the chain at the same time. This means that for [1,5] and longer rearrangements, the molecule must be able to adopt the cisoid conformation. Furthermore, there are two geometrical pathways by which any sigmatropic rearrangement can take place, which we illustrate for the case of a [1,5]-sigmatropic rearrangement,[529] starting with a substrate of the form **116**, where the migration origin is an asymmetric carbon atom and U ≠ V. In one of the two pathways, the hydrogen moves along the top or bottom face of the π system. This is called *suprafacial migration*. In the other pathway, the hydrogen moves *across* the π system, from top to bottom, or vice versa. This is *antarafacial* migration. Altogether, a single isomer like **116** (different rotamers) can give four products. In a suprafacial migration, H can move across the top of the π system (as drawn above) to give the (*R*,*Z*) isomer, or it can rotate 180° and move across the bottom of the π system to give the (*S*,*E*) isomer.[530] The antarafacial migration can similarly lead to two diastereomers, in

[526]For a monograph, see Gajewski, J.J. *Hydrocarbon Thermal Isomerizations*, Academic Press, NY, ***1981***. For reviews, see Mironov, V.A.; Fedorovich, A.D.; Akhrem, A.A. *Russ. Chem. Rev.* ***1981***, *50*, 666; Spangler, C.W. *Chem. Antarafacial

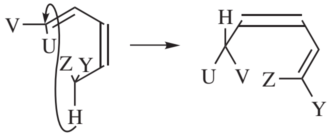
116 (*S*, *Z*) Isomer



Antarafacial

116 (*R*,*E*) Isomer

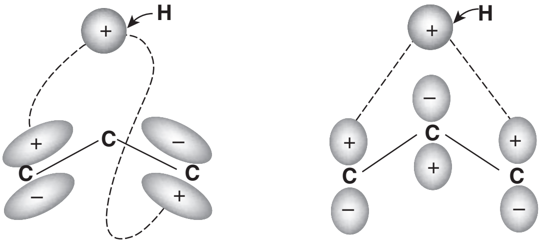
In any given sigmatropic rearrangement, only one of the two pathways is allowed by the orbital-symmetry rules; the other is forbidden. To analyze this situation, first we use a modified frontier orbital approach.[531] We will imagine that in the transition state **C**, the migrating H atom breaks away from the rest of the system, which we may treat as if it were a free radical.

C

Imaginary
transition state
for a [1,3]-
sigmatropic
rearrangement

[531]See Woodward, R.B.; Hoffmann, R. *The Conservation of Orbital Symmetry*, Academic Press, NY, ***1970***, pp. 114–140.

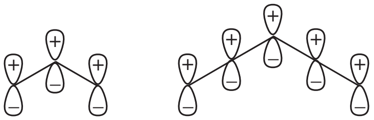
Note that this is not what actually takes place; we merely imagine it in order to be able to analyze the process. In a [1,3]-sigmatropic rearrangement, the imaginary transition state consists of a hydrogen atom and an allyl radical. The latter species (p. 42) has three π orbitals, but the only one that concerns us here is the HOMO which, in a thermal rearrangement is **D**. The electron of the hydrogen atom is of course in a 1*s* orbital, which has only one lobe. The rule governing sigmatropic migration of hydrogen is *the H must move from a plus to a plus or from a minus to a minus*



D E

lobe, of the HOMO; it cannot move to a lobe of opposite sign.[532] Obviously, the only way this can happen in a thermal [1,3]-sigmatropic rearrangement is if the migration is antarafacial. Consequently, the rule predicts that antarafacial thermal [1,3]-sigmatropic rearrangements are allowed, but the suprafacial pathway is forbidden. However, in a photochemical reaction, promotion of an electron means that **E** is now the HOMO; the suprafacial pathway is now allowed and the antarafacial pathway forbidden.

A similar analysis of [1,5]-sigmatropic rearrangements shows that in this case the thermal reaction must be suprafacial and the photochemical process antarafacial. For the general case, with odd-numbered *j*, we can say that [1,*j*]-suprafacial migrations are allowed thermally when *j* is of the form $4n + 1$, and photochemically when *j* has the form $4n - 1$; the opposite is true for antarafacial migrations.



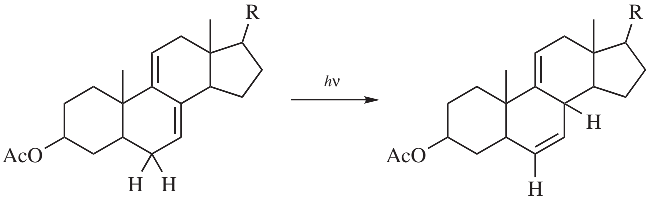
F G

As expected, the Möbius–Hückel method leads to the same predictions. Here, we look at the basis set of orbitals shown in **F** and **G** for [1,3]- and [1,5]-rearrangements, respectively. A [1,3]-shift involves four electrons, so an allowed thermal pericyclic reaction must be a Möbius system (p. 1210) with one or an odd number

[532]This follows from the principle that bonds are formed only by overlap of orbitals of the same sign. Since this is a concerted reaction, the hydrogen orbital in the transition state must overlap simultaneously with one lobe from the migration origin and one from the terminus. It is obvious that both of these lobes must have the same sign.

of sign inversions. As can be seen in **F**, only an antarafacial migration can achieve this. A [1,5]-shift, with six electrons, is allowed thermally only when it is a Hückel system with zero or an even number of sign inversions; hence it requires a suprafacial migration.[533]

The actual reported results bear out this analysis. Thus a thermal [1,3] migration is allowed to take place only antarafacially, but such a transition state would be extremely strained, and thermal [1,3]-sigmatropic migrations of hydrogen are unknown.[534] On the other hand, the photochemical pathway allows suprafacial [1,3]-shifts, and a few such reactions are known, an example being the photochemical rearrangement of **117** to **118**.[535] Substituents influence the efficacy of the [1,3]-hydrogen shift.[536]



117 **118**

The situation is reversed for [1,5]-hydrogen shifts. In this case the thermal rearrangements, being suprafacial, are quite common, while photochemical rearrangements are rare.[537] Two examples of the thermal reaction are

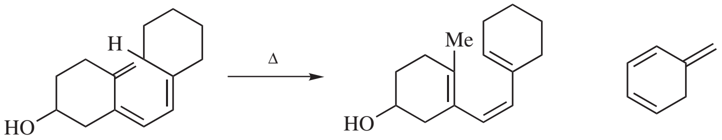
For a discussion of [1,5]-sigmatropic hydrogen shifts in cyclic 1,3-dienes, see Hess, Jr., B.A.; Baldwin, J.E. *J. Org. Chem.* ***2002***, *67*, 6025.

Note that the first example bears out the stereochemical prediction made earlier. Only the two isomers shown were formed. In the second example, migration can continue around the ring. Migrations of this kind are called *circumambulatory rearrangements*.[540] Such migrations are known for cyclopentadiene, pyrrole, and phosphole derivatives.[541] Geminal bond participation has been observed in pentadienes,[542] the effects of phenyl substituents have been studied,[543] and the kinetics and activation parameters of [1,5] hydrogen shifts have been examined.[544] The [1,5] hydrogen shifts are also known with vinyl aziridines.[545]

The rare [1,4]-hydrogen transfer has been observed in radical cyclizations.[546] With respect to [1,7]-hydrogen shifts, the rules predict the thermal reaction to be antarafacial.[547] Unlike the case of [1,3]-shifts, the transition state is not too greatly strained, and an example of such rearrangements is the formation of **119** and **120**.[548] Photochemical [1,7]-shifts are suprafacial and, not surprisingly, many of these have been observed.[549]



119 **120**

The orbital symmetry rules also help us to explain, as on pp. 1232 and 1642, the unexpected stability of certain compounds. Thus, **120** could, by a thermal [1,3]-sigmatropic rearrangement, easily convert to toluene, which of course is far more stable because it has an aromatic sextet. Yet, **120** has been prepared and is stable at dry ice temperature and in dilute solutions.[550]

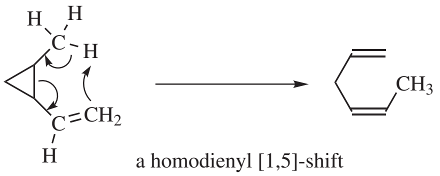
Analogs of sigmatropic rearrangements in which a cyclopropane ring replaces one of the double bonds are also known, for example,[551]



The reverse reaction has also been reported.[552] 2-Vinylcycloalkanols[553] undergo an analogous reaction, as do cyclopropyl ketones (see p. 1673 for this reaction).

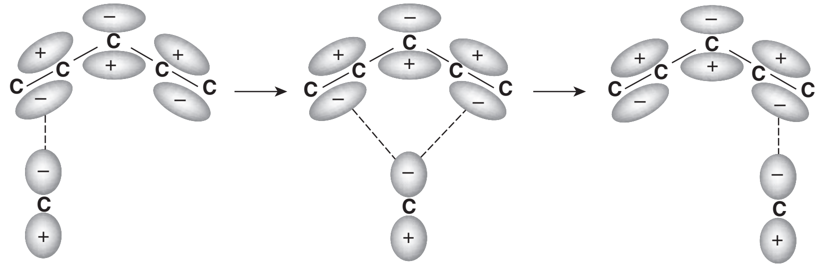

Fig. 18.5. Hypothetical orbital movement for a thermal [1,5]-sigmatropic migration of carbon. To move from one negative lobe, the migrating carbon uses only its own negative lobe, retaining its configuration.

Sigmatropic migrations of alkyl or aryl groups[556] are less common than the corresponding hydrogen migrations.[557] When they do take place, there is an important difference. Unlike a hydrogen atom, whose electron is in a 1*s* orbital with only one lobe, a carbon free radical has its odd electron in a *p* orbital that has *two lobes of opposite sign*. Therefore, if we draw the imaginary transition states for this case (see p. 1650), we see that in a thermal suprafacial [1,5] process (Fig. 18.5), symmetry can be conserved only if the migrating carbon moves in such a way that the lobe which was originally attached to the π system remains attached to the π system.

This can happen only if configuration is *retained within the migrating group*. On the other hand, thermal suprafacial [1,3] migration (Fig. 18.6) *can* take place if the migrating carbon switches lobes. If the migrating carbon was originally bonded by its minus lobe, it must now use its plus lobe to form the new C–C bond. Thus, configuration in the migrating group will be *inverted*. From these considerations we predict that suprafacial [1,*j*]-sigmatropic rearrangements in which carbon is the migrating group are always allowed, both thermally and photochemically, but that thermal [1,3] migrations will proceed with inversion and thermal [1,5]

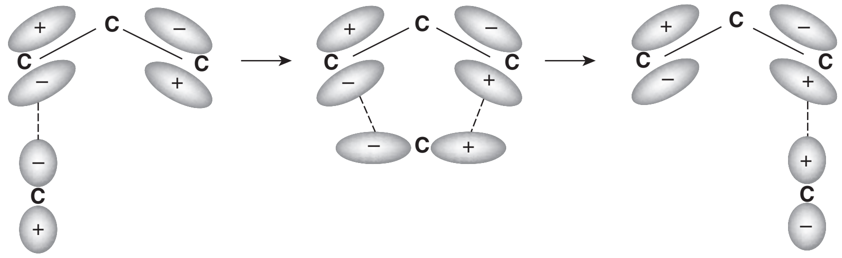

Fig. 18.6. Hypothetical orbital movement for a thermal [1,3]-sigmatropic migration of carbon. The migrating carbon moves a negative to a positive lobe, requiring it to switch its own bonding lobe from negative to positive, inverting its configuration.

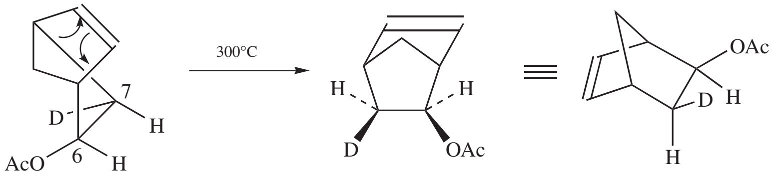
[556]For reviews, see Mironov, V.A.; Fedorovich, A.D.; Akhrem, A.A. *Russ. Chem. Rev.* ***1981***, *50*, 666; Spangler, C.W. *Chem. Rev.* ***1976***, *76*, 187

[557]It has been shown that methyl and phenyl have lower migratory aptitudes than hydrogen in thermal sigmatropic rearrangements: Shen, K.; McEwen, W.E.; Wolf, A.P. *Tetrahedron Lett.* ***1969***, 827; Miller, L.L.; Greisinger, R.; Boyer, R.F. *J. Am. Chem. Soc.* ***1969***, *91*, 1578.

migrations with retention of configuration within the migrating group. More generally, we can say that suprafacial [1,*j*] migrations of carbon in systems where $j = 4n - 1$ proceed with inversion thermally and retention photochemically, while systems where $j = 4n + 1$ show the opposite behavior. Where antarafacial migrations take place, all these predictions are of course reversed.



121 **122**

The first laboratory test of these predictions was the pyrolysis of deuterated *endo*-bicyclo[3.2.0]hept-2-en-6-yl acetate (**121**), which gave the *exo*-deuterio-*exo*-norbornyl acetate **122**.[558] Thus, as predicted by the orbital symmetry rules, this thermal suprafacial [1,3]-sigmatropic reaction took place with complete inversion at C-7. Similar results have been obtained in a number of other cases.[559] However, similar studies of the pyrolysis of the parent hydrocarbon of **121**, labeled with D at C-6 and C-7, showed that while most of the product was formed with inversion at C-7, a significant fraction (11–29%) was formed with retention.[560] Other cases of lack of complete inversion are also known.[561] A diradical mechanism has been invoked to explain such cases.[562] There is strong evidence for a radical mechanism for some [1,3]-sigmatropic rearrangements.[563] Photochemical suprafacial [1,3] migrations of carbon have been shown to proceed with retention, as predicted.[564]

Although allylic vinylic ethers generally undergo [3,3]-sigmatropic rearrangements (**18-33**), they can be made to give the [1,3] kind, to give aldehydes, for example,

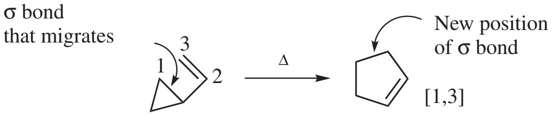
by treatment with $LiClO_4$ in diethyl ether.[565] In this case, the C–O bond undergoes a 1,3 migration from the O to the end vinylic carbon. When the vinylic ether is of the type ROCR'=CH_2, ketones RCH_2COR' are formed. There is evidence that this [1,3]-sigmatropic rearrangement is not concerted, but involves dissociation of the substrate into ions.[565]

Thermal suprafacial [1,5] migrations of carbon have been found to take place with retention,[566] but also with inversion.[567] A diradical mechanism has been suggested for the latter case.[567]

Simple nucleophilic, electrophilic, and free-radical 1,2-shifts can also be regarded as sigmatropic rearrangements (in this case, [1,2]-rearrangements). We have already (p. $$$) applied similar principles to such rearrangements to show that nucleophilic 1,2-shifts are allowed, but the other two types are forbidden unless the migrating group has some means of delocalizing the extra electron or electron pair. The mechanism of the forbidden [3s,5s]-sigmatropic shift has been examined.[568]

18-31 Conversion of Vinylcyclopropanes to Cyclopentenes



The thermal expansion of a vinylcyclopropane to a cyclopentene ring[569] is a special case of a [1,3]-sigmatropic migration of carbon, although it can also be considered an internal $[_{\pi}2 + _{\sigma}2]$-cycloaddition reaction (see **15-63**). It is known as a *vinylcyclopropane rearrangement*.[570] The reaction has been carried out on many vinylcyclopropanes bearing various substituents in the ring[571] or

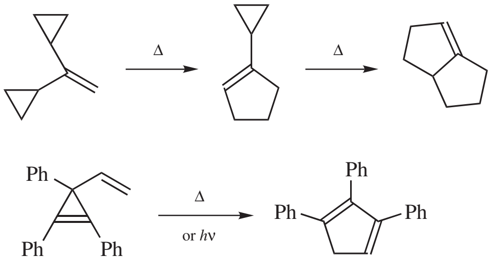
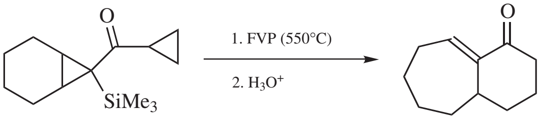
on the vinyl group and has been extended to 1,1-dicyclopropylethene[572]



and (both thermally[573] and photochemically[574]) to vinylcyclopropenes. This rearrangement can be catalyzed by rhodium and silver compounds, and has been used to form rings.[575] Another variation converts α-trimethylsilylcyclopropyl ketones to ring-expanded ketones, such as **123**, via FVP at 550°C.[576] Flash vacuum pyrolysis of the trimethylsilyl ether of cyclopropylcarbinyl alcohols gives similar results.[577] A variation uses flash vacuum pyrolysis at 600°C to convert α-trimethylsilyloxy-α-vinyl cyclic ketones to ring expanded ketones.[578]



123

Various heterocyclic analogs[579] are also known, as in the rearrangement of aziridinyl amides (**124**).[580] Cyclopropyl ketones can be treated with tosylamine and a zirconium catalyst, which converts the imine formed *in situ* to a pyrroline.[581]

Two competing reactions are the homodienyl [1,5]-shift (if a suitable H is available, see **18-29**), and simple cleavage of the cyclopropane ring, leading in this case to a diene (see **18-3**).

Vinylcyclobutanes can be similarly converted to cyclohexenes,[582] but larger ring compounds do not generally give the reaction.[583] Bicyclo[2.1.0]pentane derivatives undergo this reaction, and tricyclo[4.1.0.0^{2,5}]heptanes rearrange to give nonconjugated cycloheptadienes.[584] Though high temperatures (as high as 500°C) are normally required for the thermal reaction, the lithium salts of 2-vinylcyclopropanols rearrange to the lithium salt of cyclopent-3-enols at 25°C.[585] Salts of 2-vinylcyclobutanols behave analogously.[586]

The reaction rate has also been greatly increased by the addition of a one-electron oxidant tris-(4-bromophenyl)aminium hexafluoroantimonate $Ar_3N^{\bullet +}$ SbF_6^- (Ar = *p*-bromophenyl).[587] This reagent converts the substrate to a cation radical, which undergoes ring expansion much faster.[588]

The mechanisms of these ring expansions are not certain. Both concerted[589] and diradical[590] pathways have been proposed,[591] and it is possible that both pathways operate, in different systems.

For the conversion of a vinylcyclopropane to a cyclopentene in a different way, see OS **68**, 220.

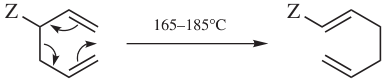
Soc.* ***1983***, *105*, 622; Klumpp, G.W.; Schakel, M. *Tetrahedron Lett.* ***1983***, *24,* 4595; McGaffin, G.; de Meijere, A.; Walsh, R. *Chem. Ber.* ***1991***, *124*, 939. A "continuous diradical transition state" has also been proposed: Roth, W.R.; Lennartz, H.; Doering, W. von E.; Birladeanu, L.; Guyton, C.A.; Kitagawa, T. *J. Am. Chem. Soc.* ***1990***, *112*, 1722, and references cited therein.

[591]For a discussion concerning whether or not this [1,3]-shift is a concerted reaction, see Gajewski, J.J.; Olson, L.P.; Willcott III, M.R. *J. Am. Chem. Soc.* ***1996***, *118*, 299. For a discussion of the mechanism of this reaction, see Su, M.-D. *Tetrahedron* ***1995***, *51*, 5871.

N-Cyclopropylimines undergo rearrangement to cyclic imines (pyrrolines) under photochemical conditions.[592] P-Vinyl phosphiranes (the P analog of cyclopropanes with P in the ring) under a similar rearrangement, and the mechanism has been studied.[593]

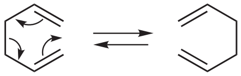
18-32 The Cope Rearrangment

(3/4/) → (1/6/)-*sigma*-Migration



Z = Ph, RCO, and so on.

When 1,5-dienes are heated, a [3,3] sigmatropic rearrangement known as the *Cope rearrangement* (not to be confused with the Cope elimination reaction, **17-9**) occurs to generate an isomeric 1,5-diene.[594] When the diene is symmetrical about the 3,4 bond, we have the unusual situation where a reaction gives a product identical with the starting material:[595]



Therefore, a Cope rearrangement can be detected only when the diene is not symmetrical about this bond. Any 1,5-diene gives the rearrangement; for example, 3-methyl-1,5-hexadiene heated to 300°C gives 1,5-heptadiene.[596] However, the reaction takes place more easily (lower temperature required) when there is a group on the 3- or 4-carbon with leads to the new double bond being substituted. The reaction is obviously reversible[597] and produces an equilibrium mixture of the two 1,5-dienes, which is richer in the thermodynamically more stable isomer. However, the equilibrium can be shifted to the right for 3-hydroxy-1,5-dienes,[598] because the product tautomerizes to the ketone or aldehyde:

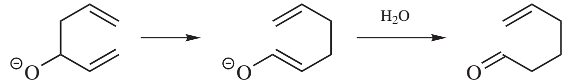
The reaction of 3-hydroxy-1,5-dienes is called the *oxy-Cope rearrangement*,[599] and has proved highly useful in synthesis.[600] The oxy-Cope rearrangement is greatly accelerated (by factors of 10^{10}–10^{17}) if the alkoxide is used rather than the alcohol (the *anionic oxy-Cope rearrangement*),[601] where the direct product is the enolate ion, which is hydrolyzed to the ketone. A metal free reaction using a phosphazene base has been reported.[602] The silyloxy-Cope rearrangement has proven to be quite useful.[603] An antibody-catalyzed oxy-Cope reaction is known,[604] and the mechanism and origins of catalysis for this reaction have been studied.[605] Sulfur substitution also leads to rate enhancement of the oxy-Cope rearrangement.[606] Note that 2-oxonia Cope rearrangements have been implicated in Prins cyclization reactions (**16-54**).[607]



aza-Cope rearrangements are also known.[608] In amino-Cope rearrangements, the solvent plays a role in the regioselectivity of the reaction.[609] It has been suggested that this latter reaction does not proceed solely by a concerted [3.3]-sigmatropic rearrangement.[610]

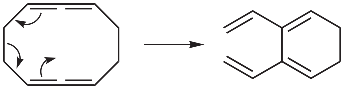
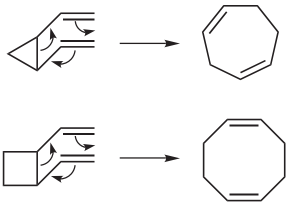
The 1,5-diene system may be inside a ring or part of an allenic system[611] (this example illustrates both of these situations):[612]



but the reaction does not take place when one of the double bonds is part of an aromatic system (e.g., 4-phenyl-1-butene).[613] When the two double bonds are in vinylic groups attached to adjacent ring positions, the product is a ring four carbons larger. This has been applied to divinylcyclopropanes and divinylcyclobutanes:[614]



Indeed, *cis*-1,2-divinylcyclopropanes give this rearrangement so rapidly that they generally cannot be isolated at room temperature,[615] though exceptions are known.[616] When heated, 1,5-diynes are converted to 3,4-dimethylenecyclobutenes **125**.[617] A rate-determining Cope rearrangement is followed by a very rapid electrocyclic (**18-27**) reaction. The interconversion of 1,3,5-trienes and cyclohexadienes

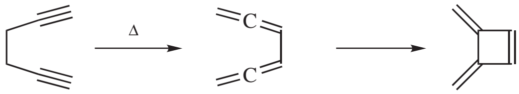
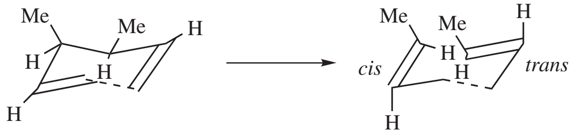
(in **18-27**) is very similar to the Cope rearrangement, but in **18-27**, the 3,4 bond goes from a double bond to a single bond rather than from a single bond to no bond.



125

Like [2 + 2]-cycloadditions (p. 1220), Cope rearrangements of simple 1,5-dienes can be catalyzed by certain transition-metal compounds. For example, the addition of $PdCl_2(PhCN)_2$ causes the reaction to take place at room temperature.[618] This can be quite useful synthetically, because of the high temperatures required in the uncatalyzed process.

As we have indicated with our arrows, the mechanism of the uncatalyzed Cope rearrangement is a simple six-centered pericyclic process.[619] Since the mechanism is so simple, it has been possible to study some rather subtle points, among them the question of whether the six-membered transition state is in the boat or the chair form.[620] For the case of 3,4-dimethyl-1,5-hexadiene, it was demonstrated conclusively that the transition state is in the chair form. This was shown by the stereospecific nature of the reaction: The meso isomer gave the cis–trans product, while the (±) diastereomer gave the trans–trans diene.[621] If the transition state is in the chair form (taking the meso isomer, e.g.), one methyl must be "axial" and the other "equatorial" and the product must be the cis–trans alkene:



[618]Overman, L.E.; Knoll, F.M. *J. Am. Chem. Soc.* ***1980***, *102*, 865; Hamilton, R.; Mitchell, T.R.B.; Rooney, J.J. *J. Chem. Soc., Chem. Commun.* ***1981***, 456. Chem.* ***1987***, *52*, 5198; Paquette, L.A.; DeRussy, D.T.; Cottrell, C.E. *J. Am. Chem. Soc.* ***1988***, *110*, 890.

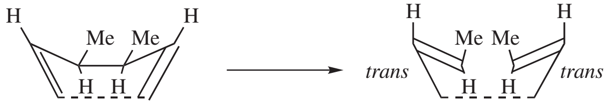
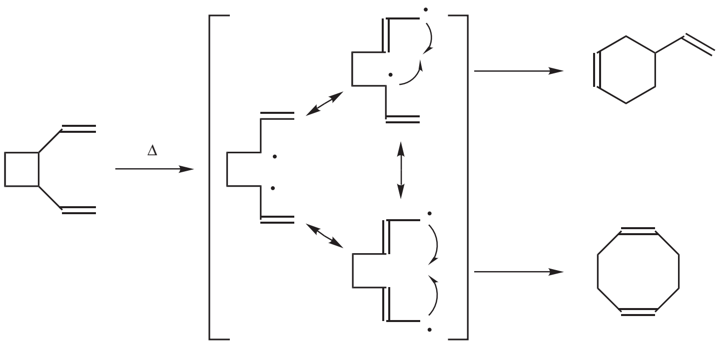
There are two possible boat forms for the transition state of the meso isomer. One leads to a trans–trans product;



the other to a cis–cis alkene. For the (±) pair the predictions are just the opposite: There is just one boat form, and it leads to the cis–trans alkene, while one chair form ("diaxial" methyls) leads to the cis–cis product and the other ("diequatorial" methyls) predicts the trans–trans product. Thus the nature of the products obtained demonstrates that the transition state is a chair and not a boat.[622] While 3,4-dimethyl-1,5-hexadiene is free to assume either the chair or boat (it prefers the chair), other compounds are not so free. Thus 1,2-divinylcyclopropane (p. 1661) can react *only* in the boat form, demonstrating that such reactions are not impossible.[623]

Because of the nature of the transition state[624] in the pericyclic mechanism, optically active substrates with a stereogenic carbon at C-3 or C-4 transfer the chirality to the product (see p. 1673 for an example in the mechanistically similar Claisen rearrangement).[625] There are many examples of asymmetric [3,3]-sigmatropic rearrangements.[626]



[622]Preference for the chair transition state is a consequence of orbital-symmetry relationships: Hoffmann, R.; Woodward, R.B. *J. Am. Chem. Soc.* ***1965***, *87*, 4389; Fukui, K.; Fujimoto, H. *Tetrahedron Lett.* ***1966***, 251.

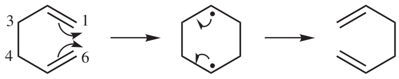
[625]For a review of Cope and Claisen reactions as enantioselective syntheses, see Hill, R.K., in Morrison, J.D. *Asymmetric Synthesis*, Vol. 3, Academic Press, NY, ***1984***, pp. 503–572, 503–545.

[626]For a review, see Nubbemeyer, U. *Synthesis* ***2003***, 961.

Not all Cope rearrangements proceed by the cyclic six-centered mechanism.[627] Thus *cis*-1,2-divinylcyclobutane (p. 1661) rearranges smoothly to 1,5-cyclooctadiene, since the geometry is favorable. The trans isomer also gives this product, but the main product is 4-vinylcyclohexene (resulting from **18-31**). This reaction can be rationalized as proceeding by a diradical mechanism,[628] although it is possible that at least part of the cyclooctadiene produced comes from a prior epimerization of the *trans*- to the *cis*-divinylcyclobutane followed by Cope rearrangement of the latter.[629]

It has been suggested that another type of diradical two-step mechanism may be preferred by some substrates.[630] Indeed, a nonconcerted Cope rearrangement has been reported.[631] In this pathway,[632] the 1,6 bond is formed before the 3,4 bond breaks:



This is related to the *Bergman cyclization* that was introduced in **18-27**.

It was pointed out earlier that a Cope rearrangement of the symmetrical 1,5-hexadiene gives 1,5-hexadiene. This is a *degenerate Cope rearrangement* (p. 1563). Another molecule that undergoes it is bicyclo[5.1.0]octadiene

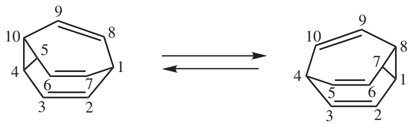
(**126**).[633] At room temperature, the NMR spectrum of this compound is in accord with the structure shown on the left. At 180°C, it is converted by a Cope reaction to a compound equivalent to itself. The interesting thing is that at 180°C the NMR spectrum shows that what exists is an equilibrium mixture of the two structures. That is, at this temperature the molecule rapidly (faster than 10^3 times per second) changes back and forth between the two structures. This is called *valence tautomerism* and is quite distinct from resonance, even though only electrons shift.[634] The positions of the nuclei are not the same in the two structures. Molecules like **126** that exhibit valence tautomerism (in this case, at 180°C) are said to have *fluxional* structures. It may be recalled that *cis*-1,2- divinylcyclopropane does not exist at room temperature because it rapidly rearranges to 1,4-cycloheptadiene (p. 1661), but in **126** the *cis*-divinylcyclopropane structure is frozen into the molecule in both structures. Several other compounds with this structural feature are also known. Of these, *bullvalene* (**127**) is especially interesting.



127

The Cope rearrangement shown changes the position of the cyclopropane ring from 4,5,10 to 1,7,8. But the molecule could also have undergone rearrangements to put this ring at 1,2,8 or 1,2,7. Any of these could then undergo several Cope rearrangements. In all, there are $\frac{10!}{3}$ or >1.2 million tautomeric forms, and the cyclopropane ring can be at any three carbons that are adjacent. Since each of these tautomers is equivalent to all the others, this has been called an infinitely degenerate Cope rearrangement. Bullvalene has been synthesized and its ^{1}H NMR spectrum determined.[635] At −25°C, there are two peaks with an area ratio of 6:4. This is in accord with a single non-tautomeric structure. The six are the vinylic protons and the four are the allylic ones. But at 100°C the compound shows only one NMR peak, indicating that we have here a truly unusual situation where the compound rapidly interchanges its structure among 1.2 million equivalent forms.[636] The ^{13}C NMR spectrum of bullvalene also shows

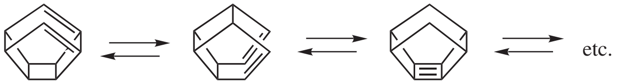
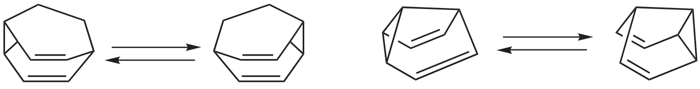
[636]A number of azabullvalenes (**127** containing heterocyclic nitrogen) have been synthesized. They also have fluxional structures when heated, though with fewer tautomeric forms than bullvalene itself: Paquette, L.A.; Malpass, J.R.; Krow, G.R.; Barton, T.J. *J. Am. Chem. Soc.* ***1969***, *91*, 5296.

only one peak at 100°C.[637]



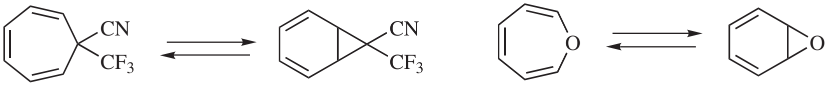
128

Another compound for which degenerate Cope rearrangements result in equivalence for all the carbons is *hypostrophene* (**128**).[638] In the case of the compound *barbaralane* (**129**)[639] (bullvalene in which one CH=CH has been replaced by a CH_2):



129 **130**

there are only 2 equivalent tautomers.[640] However, NMR spectra indicate that even at room temperature a rapid interchange of both tautomers is present, although by about −100°C this has slowed to the point where the spectrum is in accord with a single structure. In the case of *semibullvalene* (**130**) (barbaralane in which the CH_2 has been removed), not only is there a rapid interchange at room temperature, but even at −110°C.[641] Compound **130** has the lowest energy barrier of any known compound capable of undergoing the Cope rearrangement.[642]



131 **132** Oxepin Benzene oxide

For a discussion concerning whether or not semibullvalenes are homoaromatic, see Williams, R.V.; Gadgil, V.R.; Chauhan, K.; Jackman, L.M.; Fernandes, E. *J. Org. Chem.* ***1998***, *63*, 3302.

The molecules taking part in a valence tautomerization need not be equivalent. Thus, NMR spectra indicate that a true valence tautomerization exists at room temperature between the cycloheptatriene **131** and the norcaradiene **132**.[643] In this case, one isomer (**132**) has the *cis*-1,2-divinylcyclopropane structure, while the other does not. In an analogous interconversion, benzene oxide[644] and oxepin exist in a tautomeric equilibrium at room temperature.[645]

Bullvalene and hypostrophene are members of a group of compounds all of whose formulas can be expressed by the symbol $(CH)_{10}$.[646] Many other members of this group are known. Similar groups of $(CH)_n$ compounds exist for other even-numbered values of "*n*".[646] For example, there are 20 possible $(CH)_8$[647] compounds,[648] and five possible $(CH)_6$ compounds,[649] all of which are known: benzene, prismane (p. 220), Dewar benzene (p. 1641), bicyclopropenyl,[650] and benzvalene.[651]

An interesting example of a valence tautomerism is the case of 1,2,3-tri-*tert*-butylcyclobutadiene (p. 74). There are two isomers, both rectangular, and ^{13}C NMR spectra show that they exist in a dynamic equilibrium, even at −185°C.[652]

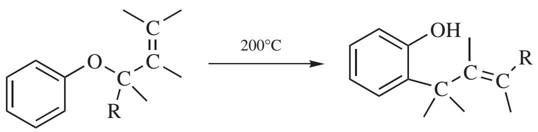
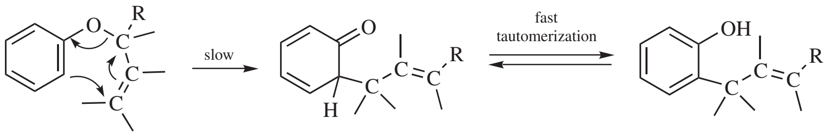
18-33 The Claisen Rearrangement[653]



Allylic aryl ethers, when heated, rearrange to *o*-allylphenols in a reaction called the *Claisen rearrangement*.[654] If both ortho positions are filled, the allylic group migrates to the para position (this is often called the *para-Claisen rearrangement*).[655] There is no reaction when the para and both ortho positions are filled. Migration to the meta position has not been observed. In the ortho migration, the allylic group always undergoes an allylic shift. That is, as shown above, a substituent α to the oxygen is now γ to the ring (and vice versa). On the other hand, in the para migration there is never an allylic shift: The allylic group is found exactly as it was in the original ether. Compounds with propargylic groups (i.e., groups with a triple bond in the appropriate position) do not generally give the corresponding products.

The mechanism is a concerted pericyclic [3,3]-sigmatropic rearrangement[656] and accounts for all these facts. For the ortho rearrangement:



Evidence is the lack of a catalyst, the fact that the reaction is first order in the ether, the absence of crossover products when mixtures are heated, and the presence of the allylic shift, which is required by this mechanism. A *retro*-Claisen rearrangement is known and its mechanism has been examined.[657] The allylic

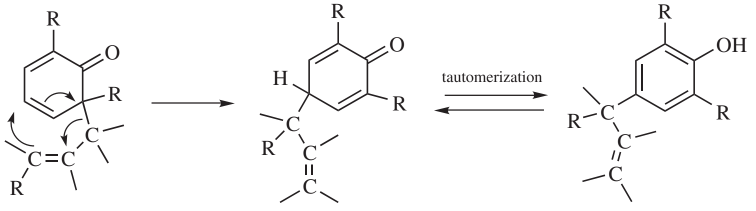
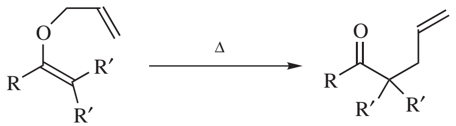
shift for the ortho rearrangement (and the absence of one for the para) has been demonstrated by ^{14}C labeling, even when no substituents are present. Studies of the transition-state geometry have shown that, like the Cope rearrangement, the Claisen rearrangement usually prefers a chair-like transition state.[658] When the ortho positions have no hydrogen, a second [3,3]-sigmatropic migration (a Cope reaction) follows:



133

and the migrating group is restored to its original structure. Intermediates of structure **133** have been trapped by means of a Diels–Alder reaction.[659] The rearrangement of aryl allyl ethers is facilitated by Ag–KI in hot acetic acid,[660] and by $AlMe_3$ in water.[661] A solid-phase reaction of polymer-bound substrate undergoes the Claisen rearrangement with microwave irradiation.[662]

Allylic ethers of enols (allylic vinylic ethers) also undergo the Claisen rearrangement;[663] in fact, it was discovered with these compounds first:[664]



In these cases of course, the final tautomerization does not take place even when R' = H, since there is no aromaticity to restore, and ketones are more stable than enols.[665] Catalytic Claisen rearrangements of allyl vinyl ethers are well known.[666]

[665]However, it has proved possible to reverse the reaction, with a Lewis acid catalyst. See Boeckman Jr., R.K.; Flann, C.J.; Poss, K.M. *J. Am. Chem. Soc.* ***1985***, *107*, 4359.

[666]For a review, see Hiersemann, M.; Abraham, L. *Eur. J. Org. Chem.* ***2002***, 1461.

The use of water as solvent accelerates the reaction.[667] A microwave induced reaction on silica gel is known[668]. The mechanism is similar to that with allylic aryl ethers.[669] Allyl allene ethers undergo a Claisen rearrangement when heated in DMF to give the expected diene with a conjugated aldehyde unit.[670] Butenolides with a β-allylic ether unit undergo Claisen rearrangement–Conia reaction[671] cascade to give an oxaspiro heptane with β-keto lactone comprising the five-membered ring.[672] Allylic esters of β-keto acids undergo a Claisen rearrangement in what is known as the *Carroll rearrangement*[673] (also called the *Kimel–Cope rearrangement*[674]), and the reaction can be catalyzed by a ruthenium complex.[675]

It is possible to treat ketones with allyl alcohol and an acid catalyst to give γ,δ-unsaturated ketones directly, presumably by initial formation of the vinylic ethers, and then Claisen rearrangement.[676] In an analogous procedure, the enolates (**134**) of allylic esters [formed by treatment of the esters with lithium isopropylcyclohexylamide (LICA)] rearrange to γ,δ-unsaturated acids.[677] Allylic alcohols can be treated with a catalytic amount of mercuric acetate, and in the presence of an excess of allyl vinyl ethers give an alkene–aldehyde via a Claisen rearrangement.[678]

Alternatively, the silylketene acetal $R^3R^2C{=}C(OSiR_3)OCH_2CH{=}CHR^1$ is often used instead of **134**.[677,679] This rearrangement also proceeds at room temperature. By either procedure, the reaction is called the *Ireland–Claisen rearrangement*.[680] Note the presence of the negative charge in **134**. As with the oxy-Cope rearrangement (in **18-34**), negative charges generally accelerate the Claisen reaction,[681] although the extent of the acceleration can depend on the identity of the positive counterion.[682] The reaction proceeds with good syn selectivity in many cases.[683] The Ireland–Claisen rearrangement has been made enantioselective by converting **134** to an enol borinate in which the boron is attached to a chiral group.[684] The Ireland–Claisen rearrangement can be done with amide derivatives also.[685]

A number of expected analogs of the Claisen rearrangement are known, for example, rearrangement of $ArNHCH_2CH{=}CH_2$,[686] of *N*-allylic enamines ($R_2C{=}CRNRCR_2CR{=}CR_2$),[687] of allylic imino esters, $RC(OCH_2CH{=}CH_2){=}NR$[688] (these have often been rearranged with transition-metal catalysts[689]), and of $RCH{=}NRCHRCH_2CH{=}CH_2$. These rearrangements of nitrogen-containing compounds can be called *aza-Claisen rearrangements*,[690] but are often called

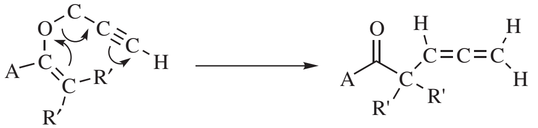
aza-Cope rearrangements[691] as described in **18-34**. However, a palladium catalyzed aza-Claisen has been reported.[692] A so-called amine-Claisen rearrangement was reported for *N*-allyl indoles, when heated in the presence of $BF_3{\bullet}OEt_2$.[693] An *azo-Cope* rearrangement: $CH_2{=}CHCR^1_2\ CR^2_2\ N{=}NAr \rightarrow R^1_2C{=}CHCH_2NArN{=}CR^2_2$ has been reported.[694] Propargylic vinylic compounds give allenic aldehydes, ketones, esters, or amides:[695]



The conversion of allylic aryl thioethers $ArSCH_2CH{=}CH_2$ to *o*-allylic thiophenols is not feasible, because the latter are not stable,[696] but react to give bicyclic compounds.[697] However, many allylic vinylic sulfides do give the rearrangement (the *thio-Claisen rearrangement*).[698] Allylic vinylic sulfones, for example, $H_2C{=}CRCH_2{-}SO_2{-}CH{=}CH_2$, rearrange, when heated in the presence of ethanol and pyridine, to unsaturated sulfonate salts $CH_2{=}CRCH_2CH_2CH_2SO_3^-$, produced by reaction of the reagents with the unstable sulfene intermediates $CH_2{=}CRCH_2CH_2CH{=}SO_2$.[699] Allylic vinylic sulfoxides rapidly rearrange at room temperature or below.[700]

As mentioned for the Ireland–Claisen rearrangement, asymmetric Claisen rearrangement reactions are well known.[701] Chiral Lewis acids have been designed for

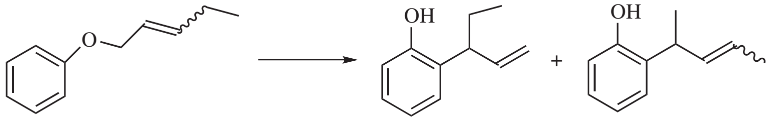
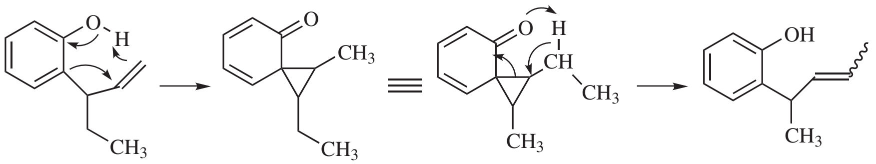
this purpose.[702] In general, asymmetric [3,3]-sigmatropic rearrangements are well known.[703]

Ethers with an alkyl group in the γ position (ArO–C–C=C–R systems) sometimes give abnormal products, with the β carbon becoming attached to the ring:[704]

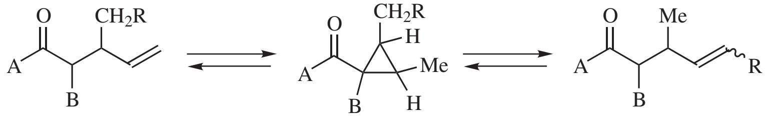


Normal product Abnormal product

It has been established that these abnormal products do not arise directly from the starting ether, but are formed by a further rearrangement of the normal product:[705]



This rearrangement, which has been called an *enolene rearrangement*, a *homodienyl* [1,5]-*sigmatropic hydrogen shift* (see **18-29**), and a [1,5]-*homosigmatropic rearrangement*, involves a shift of three electron pairs over *seven* atoms. It has been found that this "abnormal" Claisen rearrangement is general and can interconvert the enol forms of systems of the types **135** and **136** through the cyclopropane intermediate **137**.[706]



135 **136** **137**

A = H, R, Ar, OR, and so on

Since the Claisen rearrangement mechanism does not involve ions, it should not be greatly dependent on the presence or absence of substituent groups on the ring.[707] This is the case. Electron-donating groups increase the rate and electron-withdrawing groups decrease it, but the effect is small, with the *p*-amino compound reacting only ~10–20 times faster than the *p*-nitro compound.[708] However, solvent effects[709] are greater: Rates varied over a 300-fold range when the reaction was run in 17 different solvents.[710] An especially good solvent is trifluoroacetic acid, in which the reaction can be carried out at room temperature.[711] Most Claisen rearrangements are performed without a catalyst, but $AlCl_3$ or BF_3 are sometimes used.[712] In this case, it may become a Friedel–Crafts reaction, with the mechanism no longer cyclic,[713] and ortho, meta, and para products may be obtained.

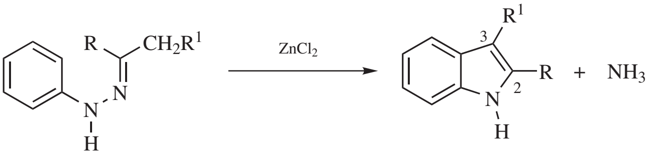
18-34 The Fischer Indole Synthesis



When arylhydrazones of aldehydes or ketones are treated with a catalyst, elimination of ammonia takes place and an indole is formed, in the *Fischer indole synthesis*.[714] Zinc chloride is the catalyst most frequently employed, but dozens of others, including other metal halides, proton and Lewis acids, and certain transition

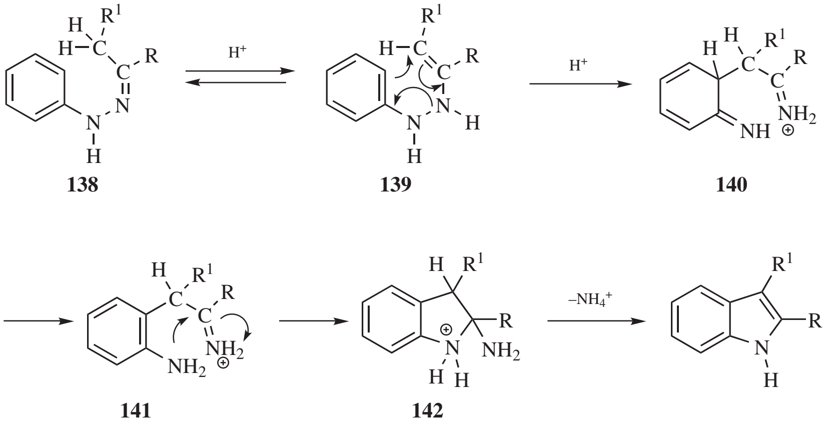
metals have also been used. Microwave irradiation has been used to facilitate this reaction.[715] The reaction has been done using an $AlCl_3$ complex as an ionic liquid,[716] and solid-phase Fischer-indole syntheses are known.[717] Aniline derivatives react with α-diazoketones, in the presence of a rhodium catalyst, to give indoles as well.[718] Arylhydrazones are easily prepared by the treatment of aldehydes or ketones with phenylhydrazine (**16-2**) or by aliphatic diazonium coupling (**12-7**). However, it is not necessary to isolate the arylhydrazone. The aldehyde or ketone can be treated with a mixture of phenylhydrazine and the catalyst; this is now common practice. In order to obtain an indole, the aldehyde or ketone must be of the form $RCOCH_2R'$ (R = alkyl, aryl, or hydrogen). Vinyl ethers, such as dihydrofuran, serves as an aldehyde surrogate when treated with phenylhydrazine and a catalytic amount of aqueous sulfuric acid to give an 3-substituted indole.[719]

At first glance, the reaction does not seem to be a rearrangement. However, the key step of the mechanism[720] is a [3,3]-sigmatropic rearrangement:[721]



There is much evidence for this mechanism, for example, (*1*) the isolation of **142**,[722] (*2*) the detection of **141** by ^{13}C and ^{15}N NMR,[723] (*3*) the isolation of side products that could only have come from **140**,[724] and (*4*) ^{15}N labeling experiments that showed

that it was the nitrogen farther from the ring that is eliminated as ammonia.[725] The main function of the catalyst seems to be to speed the conversion of **138** to **139**. The reaction can be performed without a catalyst.

There are alternative methods to produce indoles. Acetophenone reacts with 2-chloro nitrobenzene derivatives in the presence of a phenol and a palladium catalyst to give an indole.[726]

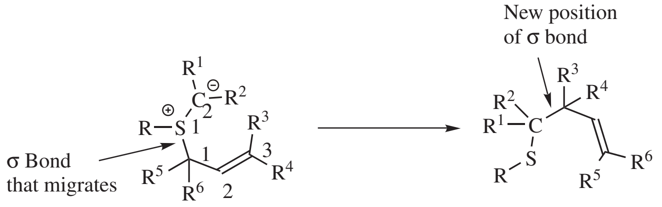
18-35 [2,3]-Sigmatropic Rearrangements

(2/*S*-3/) → (1/5/)-*sigma*-Migration



Sulfur ylids bearing an allylic group are converted on heating to unsaturated sulfides.[727] This is a concerted [2,3]-sigmatropic rearrangement[728] and has also been demonstrated for the analogous cases of nitrogen ylids[729] and the conjugate bases of allylic ethers (in the last case it is called the *[2,3]-Wittig rearrangement*).[730] It has been argued that the [2,3]-Wittig rearrangement demands severe deformation of the molecule in order to proceed.[731] The SmI_2 compound has been shown to induce

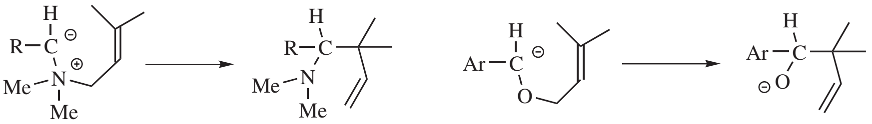
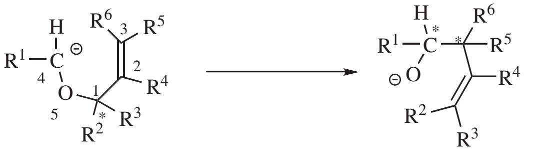
a [2,3]-Wittig rearrangement.[732] The reaction has been extended to certain other systems,[733] even to an all-carbon system.[734]



Since the reactions involve migration of an allylic group from a sulfur, nitrogen, or oxygen atom to an adjacent negatively charged carbon atom, they are special cases of the Stevens or Wittig rearrangements (**18-21**, **18-22**). However, in this case the migrating group *must* be allylic (in **18-21** and **18-22** other groups can also migrate). Thus, when the migrating group is allylic, there are two possible pathways: (*1*) the radical-ion or ion-pair mechanisms (**18-21**, **18-22**) and (*2*) the concerted pericyclic [2,3]-sigmatropic rearrangement. These can easily be told apart, since the latter always involves an allylic shift (as in the Claisen rearrangement), while the former pathway does not.



Of these reactions, the [2,3]-Wittig rearrangement in particular has often been used as a means of transferring chirality. The product of this reaction has potential stereogenic centers at C-3 and C-4 (if $R^5 \neq R^6$), and if the starting ether is optically active because of a stereogenic center at C-1, the product may be optically active as well. Many examples are known in which an optically active ether was converted to a product that was optically active because of chirality at C-3, C-4, or both.[735] If a

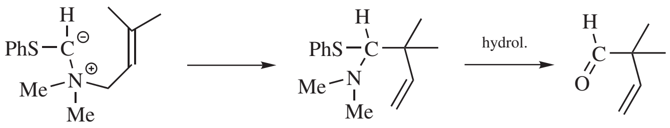
suitable stereogenic center is present in R^1 (or if a functional group in R^1 can be so converted), then stereocontrol over three contiguous stereogenic centers can be achieved. Stereocontrol of the new double bond (*E* or *Z*) has also been accomplished.

If an OR or SR group is attached to the negative carbon, the reaction becomes a method for the preparation of β,γ-unsaturated aldehydes, because the product is easily hydrolyzed.[736]



Another [2,3]-sigmatropic rearrangement converts allylic sulfoxides to allylically rearranged alcohols by treatment with a thiophilic reagent, such as trimethyl phosphite.[737] This is often called the *Mislow–Evans rearrangement*. In this case, the migration is from sulfur to oxygen. [2,3]-Oxygen-to-sulfur migrations are also known.[738] The Sommelet–Hauser rearrangement (**13-31**) is also a [2,3]-sigmatropic rearrangement.

When hydrazobenzene is treated with acids, it rearranges to give ~70% 4,4′-diaminobiphenyl (**143**, benzidine) and ~30% 2,4′-diaminobiphenyl. This reaction is called the *benzidine rearrangement* and is general for *N,N′*-diarylhydrazines.[739] Usually, the major product is the 4,4′-diaminobiaryl, but four other products may also be produced. These are the 2,4′-diaminobiaryl, already referred to, the 2,2′-diaminobiaryl, and the *o*- and *p*-arylaminoanilines (called *semidines*). The 2,2′- and *p*-arylaminoaniline compounds are formed less often and in smaller amounts than the other two side products. Usually, the 4,4′-diaminobiaryl predominates, except when one or both para positions of the diarylhydrazine are occupied. However, the 4,4′-diamine may still be produced even if the para positions are occupied. If SO_3H, COOH, or Cl (but not R, Ar, or NR_2) is present in the para position, it may be ejected. With dinaphthylhydrazines, the major products are not the 4,4′-diaminobinaphthyls, but the 2,2′ isomers. Another side reaction is disproportionation to $ArNH_2$ and ArN=NAr. For example, *p,p′*-$PhC_6H_4NHNHC_6H_4Ph$ gives 88% disproportionation products at 25°C.[740]

The mechanism has been exhaustively studied and several mechanisms have been proposed.[741] At one time, it was believed that NHAr broke away from ArNHNHAr and became attached to the para position to give the semidine, which then went on to product. The fact that semidines could be isolated lent this argument support, as did the fact that this would be analogous to the rearrangements considered in Chapter 11 (**11-28–11-32**). However, this theory was killed when it was discovered that semidines could not be converted to benzidines under the reaction conditions. Cleavage into two independent pieces (either ions or radicals) has been ruled out by many types of crossover experiments, which always showed that the two rings of the starting material are in the product; that is, ArNHNHAr′ gives no molecules (of any of the five products) containing two Ar groups or two Ar′ groups, and mixtures of ArNHNHAr and Ar′NHNHAr′ give no molecules containing both Ar and Ar′. An important discovery was the fact that, although the reaction is always first order in substrate, it can be either

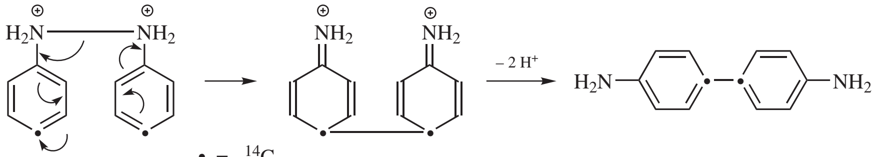
first[742] or second[743] order in [H^+]. With some substrates the reaction is entirely first order in [H^+], while with others it is entirely second order in [H^+], regardless of the acidity. With still other substrates, the reaction is first order in [H^+] at low acidities and second order at higher acidities. With the latter substrates fractional orders can often be observed,[744] because at intermediate acidities, both processes take place simultaneously. These kinetic results seem to indicate that the actual reacting species can be either the monoprotonated substrate $ArNHNH_2Ar$ or the diprotonated $ArNH_2NH_2Ar$.

Most of the proposed mechanisms[745] attempted to show how all five products could be produced by variations of a single process. An important breakthrough was the discovery that the two main products are formed in entirely different ways, as shown by isotope-effect studies.[746] When the reaction was run with hydrazobenzene labeled with ^{15}N at both nitrogen atoms, the isotope effect was 1.022 for formation of **143**, but 1.063 for formation of 2,4′-diaminobiphenyl. This showed that the N–N bond is broken in the rate-determining step in both cases, but the steps themselves are obviously different. When the reaction was run with hydrazobenzene labeled with ^{14}C at a para position, there was an isotope effect of 1.028 for formation of **143**, but essentially no isotope effect (1.001) for formation of 2,4′-diaminobiphenyl. This can only mean that for **143** formation of the new C–C bond *and* breaking of the N–N bond both take place in the rate-determining step; in other words, the mechanism is concerted. The following [5.5]-sigmatropic rearrangement accounts for this:[745,747]



• = ^{14}C

[747]This step was also part of the "polar-transition-state mechanism".

The diion **144** was obtained as a stable species in super acid solution at −78°C by treatment of hydrazobenzene with $FSO_3H–SO_2$ (SO_2ClF).[748] Though the results just given were obtained with hydrazobenzene, which reacts by the diprotonated pathway, monoprotonated substrates have been found to react by the same [5,5]-sigmatropic mechanism.[749] Some of the other rearrangements in this section are also sigmatropic. Thus, formation of the *p*-semidine takes place by a [1,5]-sigmatropic rearrangement,[750] and the conversion of 2,2′-hydrazonaphthalene to 2,2′-diamino-1,1′-binaphthyl by a [3,3]-sigmatropic rearrangement.[751]

2,4′-Diaminobiphenyl is formed by a completely different mechanism, though the details are not known. There is rate-determining breaking of the N–N bond, but the C–C bond is not formed during this step.[752] The formation of the *o*-semidine also takes place by a nonconcerted pathway.[753] Under certain conditions, benzidine rearrangements have been found to go through radical cations.[754]

C. Other Cyclic Rearrangements

18-37 Metathesis of Alkenes (Alkene or Olefin Metathesis)[755]

Alkene metathesis

$$CH_3CH{=}CHCH_2CH_3 \xrightarrow[WCl_6–EtOH]{EtAlCl_2} CH_3CH{=}CHCH_3 + CH_3CH_2CH{=}CHCH_2CH_3$$

When alkenes are treated with certain catalysts they are converted to other alkenes in a reaction in which the alkylidene groups ($R^1R^2C{=}$) have become interchanged by a process schematically illustrated by the equation:

The reaction is called *metathesis* of alkenes or *alkene metathesis* (*olefin metathesis*).[756] In the example shown above, 2-pentene (either cis, trans, or a cis–trans mixture) is converted to a mixture of ~50% 2-pentene, 25% 2-butene, and 25% 3-hexene. The reaction is reversible[757] and the alkene starting material and products exist in an equilibrium, so the same mixture can be obtained by starting with equimolar quantities of 2-butene and 3-hexene.[758] In general, the reaction can be applied to a single unsymmetrical alkene, giving a mixture of itself and two other alkenes, or to a mixture of two alkenes, in which case the number of different molecules in the product depends on the symmetry of the reactants. As in the case above, a mixture of $R^1R^2C{=}CR^1R^2$ and $R^3R^4C{=}CR^3R^4$ gives rise to only one new alkene ($R^1R^2C{=}CR^3R^4$), while in the most general case, a mixture of $R^1R^2C{=}CR^3R^4$ and $R^5R^6C{=}CR^7R^8$ gives a mixture of 10 alkenes: the original $2 + 8$ new ones. In early work, tungsten, molybdenum,[759] or rhenium complexes were used, and with simple alkenes the proportions of products are generally statistical,[760] which limited the synthetic utility of the reaction

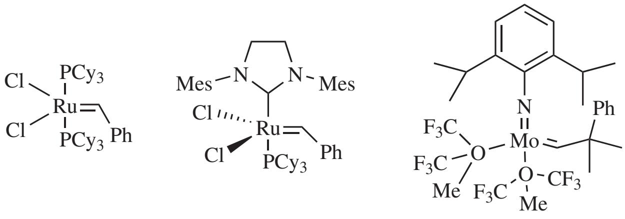
since the yield of any one product is low. However, in some cases one alkene may be more or less thermodynamically stable than the rest, so that the proportions are not statistical. Furthermore, it may be possible to shift the equilibrium. For example, 2-methyl-1-butene gives rise to ethylene and 3,4-dimethyl-3-hexene. By allowing the gaseous ethylene to escape, the yield of 3,4-dimethyl-3-hexene can be raised to 95%.[761]



145 **146** **147**

The development of new catalysts have revolutionized this reaction, making it one of the most important methods available for synthesis. Tailoring the substrate to include two terminal alkenes leads to ethylene as a product, whose escape from the reaction drives the equilibrium to product. Many catalysts, both homogeneous[762] and heterogeneous,[763] have been used for this reaction. Although there are several examples of the former, ruthenium complexes are the most important,[764] while among the latter are oxides of Mo, W, and Re deposited on alumina or silica gel.[765] The major breakthrough in these catalysts was the development of catalysts that are relatively air stable. The three most used catalysts are carbene complexes **145**[766] and **146**[767] (Grubbs catalysts I and II, respectively), and **147** (the Shrock catalyst).[768] Catalyst **146** can be generated *in situ* from air stable

precursors. [769] Recyclable catalyst have been developed,[770] and the reaction has been done in ionic liquids,[771] as well as supercritical CO_2[772] (p. 414). Microwave-induced ring-closing metathesis reactions are known.[773] Polymer-bound ruthenium catalysts[774] and molybdenum catalysts[775] have been used, and the **146** has been immobilized on polyethylene glycol, PEG).[776] Efficient methods have been developed for the removal of ruthenium by-products from metathesis reactions.[777] By choice of the proper catalyst, the reaction has been applied to terminal and internal alkenes, straight chain or branched. The effect of substitution on the ease of reaction is $CH_2{=} > RCH_2CH{=} > R_2CHCH{=} > R_2C{=}$.[778] Note that isomerization of the C=C unit can occur after metathesis.[779] Cross-metathesis[780,781] (or symmetrical homo-metathesis[782]) of alkenes to give new alkenes

can be accomplished with the modern metathesis catalysts. Monosubstiuted alkenes react faster than disubstituted alkenes.[783] A double metathesis reaction of a diene (also called domino metathesis[784] or tandem metathesis[785]) with conjugated aldehydes has been reported,[786] and a triple-metathesis was reported to for a dihydropyran with two dihydropyran substituents.[787] Cross-metathesis of a terminal alkyne and a terminal alkenes (en-ynes)[788] to give a diene has also been reported.[789] Cross-metathesis of vinylcyclopropanes leads to an alkene with two cyclopropyl substituents.[790] Vinylcyclopropane-alkyne metathesis reactions have been reported.[791]Cyclic alkenes can be opened, usually with polymerization using metathesis catalysts. Ring-opening metathesis generates dienes from cyclic alkenes.[792] Allenes undergo a metathesis reaction to give symmetrical allenes.[793] The Grubbs catalyst is compatible with forming cyclic alkenes by ring-closing metathesis followed by treatment with hydrogen to give the saturated cyclic compound.[794] An interesting variation reacts an α,ω-diene with a cyclic alkene. The combination of ring-opening metathesis and ring-closing cross-metathesis leads to ring expansion to give a macrocyclic nonconjugated diene.[795]

Dienes can react intermolecularly or intramolecularly.[796] Intramolecular reactions generate rings, usually alkenes or dienes. Alkene metathesis can be

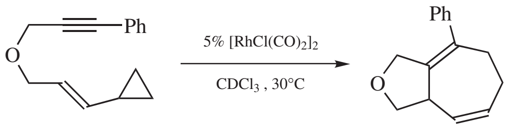
used to form very large rings, including 21-membered lactone rings.[797] Diynes can also react intramolecularly to give large-ring alkynes.[798] Metathesis with vinyl-cyclopropyl-alkynes is also known, producing a ring expanded product (see **148**).[799]



148

The synthetic importance of ring-closing and ring-opening metathesis reactions has led to the development of several new catalysts.[800] Catalysts have been developed that are compatible with both water and methanol.[801] The reaction is compatible with the presence of other functional groups,[802] such as other alkene units,[803] carbonyl units,[804] the alkene unit of conjugated esters,[805] butenolides[806] and other lactones,[807] amines,[808] amides,[809] sulfones,[810] phosphine oxides,[811] sulfonate esters,[812] and sulfonamides[813]

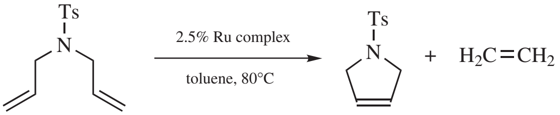
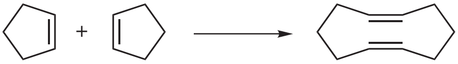
(see **149**).[814] Ether groups,[815] including vinyl ethers,[816] vinyl halides,[817] vinyl silanes,[818] vinyl sulfones,[819] allylic ethers,[820] and thioethers[821] are also compatible. Asymmetric ring-closing metathesis reactions have been reported.[822] Asymmetric ring-opening metathesis has also been reported.[823]



149

Two cyclic alkenes react to give dimeric dienes,[824] for example,



However, the products can then react with additional monomers and with each other, so that polymers are generally produced, and the cyclic dienes are obtained only in low yield. The reaction between a cyclic and a linear alkene can give an ring-opened diene:[825]

Alkenes containing functional groups[826] do not give the reaction with most of the common catalysts, but some success has been reported with WCl_6–$SnMe_4$[827] and with certain other catalysts.

The reaction has also been applied to internal triple bonds:[828]

$$2\,RC{\equiv}CR' \rightleftharpoons RC{\equiv}CR + R'C{\equiv}CR'$$

but it has not been successful for terminal triple bonds,[829] although as noted above, molecules with a terminal alkene and a terminal alkyne react quite well. Ring-closing metathesis of alkene–alkynes leads to a cyclic alkene with a pendant vinyl unit (a diene).[830] Intramolecular reactions of a double bond with a triple bond are known[831] and a tetracyclic tetraene has been prepared from a poly-yne-diene.[832]

The generally accepted mechanism is a chain mechanism,[833] involving the intervention of a metal–carbene complex (**150** and **151**)[834] and a four-membered ring

containing a metal[835] (**152–155**).[836] In the cross-metathesis reaction shown as an example, $R_2C{=}CR_2$ reacts with $R^1{}_2C{=}CR^1{}_2$ in the presence of a metal catalyst, M. Initial reaction with the catalyst leads to the two expected metal carbenes, **150** and **151**. Metal carbene **151** can react with both alkenes to form metallocyclobutanes **152** and **153**. Each of these intermediates loses the metal to form the alkenes, the product of metathesis $R_2C{=}CR^1{}_2$ and the one of the original alkenes. In a likewise manner, **150** reacts with each alkene to form metallocyclobutanes **154** and **155**, which decomposes to $R_2C{=}CR_2$ and the metathesis product.

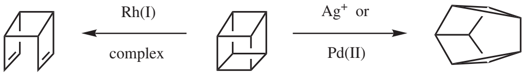
18-38 Metal-Ion-Catalyzed σ-Bond Rearrangements



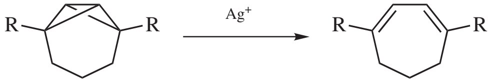
156 Cubane Cuneane

Many highly strained cage molecules undergo rearrangement when treated with metallic ions, such as Ag^+, Rh(I), or Pd(II).[837] The bond rearrangements observed can be formally classified into two main types: (*1*) [2+2]-ring

Type 1 Type 2

openings of cyclobutanes and (*2*) conversion of a bicyclo[2.2.0] system to a bicyclopropyl system. The molecule cubane supplies an example of each type (see above). Treatment with Rh(I) complexes converts cubane to tricyclo[4.2.0.0^{2,5}]octa-3,7-diene (**156**),[838] an example of type 1, while Ag^+ or Pd(II) causes the second type of reaction, producing cuneane.[839] Other examples are

Type 1



157 **158**

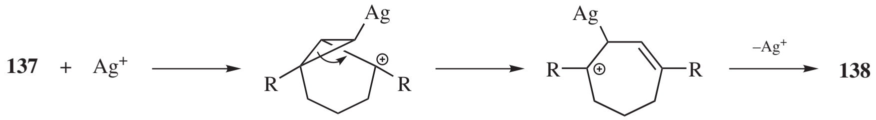
Type 2 [841]  Ref. [842]

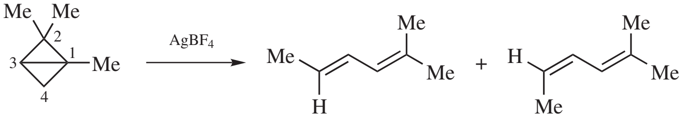
159

159 is the 9,10-dicarbomethyoxy derivative of *snoutane* (pentacyclo[3.3.2.0^{2,4}.0^{3,7}.0^{6,8}] decane).

The mechanisms of these reactions are not completely understood, although relief of strain undoubtedly supplies the driving force. The reactions are thermally forbidden by the orbital-symmetry rules, and the role of the catalyst is to provide low-energy pathways so that the reactions can take place. The type 1 reactions are the reverse of the catalyzed [2 + 2] ring closures discussed at **15-63**. The following mechanism, in which Ag^+ attacks one of the edge bonds, has been suggested for the conversion of **157** to **158**.[843]



Simpler bicyclobutanes can also be converted to dienes, but in this case the products usually result from cleavage of the central bond and one of the edge bonds.[844] For example, treatment of **160** with $AgBF_4$,[845]



160

[841]The starting compound here is a derivative of basketane, or 1,8-bishomocubane. For a review of homo-, bishomo-, and trishomocubanes, see Marchand, A.P. *Chem. Rev.* ***1989***, *89*, 1011.

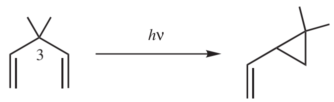
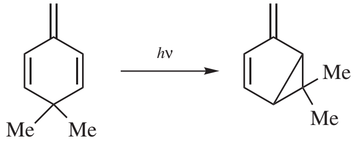
or [(π-allyl)PdCl]$_2$[846] gives a mixture of the two dienes shown, resulting from a formal cleavage of the C_1–C_3 and C_1–C_2 bonds (note that a hydride shift has taken place). Dienes can also be converted to bicyclobutanes under photochemical conditions.[847]

18-39 The Di-π-methane and Related Rearrangements

Di-π-methane rearrangement



1,4-Dienes carrying alkyl or aryl substituents on C-3[848] can be photochemically rearranged to vinylcyclopropanes in a reaction called the *di-π-methane rearrangement*.[849] An example is conversion of **161** to **162**.[850] For most



161 **162**

1,4-dienes it is only the singlet excited states that give the reaction; triplet states generally take other pathways.[851] For unsymmetrical dienes, the reaction is regioselective. For example, **163** gave **164**, not **165**:[852]

[846]Gassman, P.G.; Meyer, R.G.; Williams, F.J. *Chem. Commun.* ***1971***, 842.

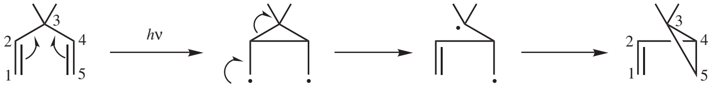
163 **164** **165** Not formed

The mechanism can be described by the diradical pathway given[853] (the C-3 substituents act to stabilize the radical), though the species shown are not necessarily intermediates, but may be transition states. It has been shown, for the case of certain substituted substrates, that configuration is retained at C-1 and C-5 and inverted at C-3.[854]



The reaction has been extended to allylic benzenes[855] (in this case C-3 substituents are not required), to β,γ-unsaturated ketones[856] (the latter reaction, which is called the *oxa-di-π-methane rearrangement*,[857] generally occurs only from the triplet state), to β,γ-unsaturated imines,[858] and to triple-bond systems.[859]

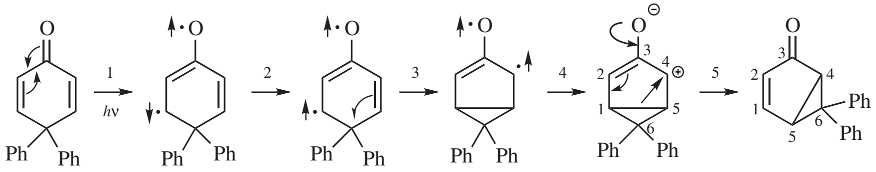
When photolyzed, 2,5-cyclohexadienones can undergo a number of different reactions, one of which is formally the same as the di-π-methane rearrangement.[860] In this reaction, photolysis of the substrate **166** gives the bicyclo[3.1.0]hexenone (**171**). Although the reaction is formally the same (note the conversion of **161** to **162**



166 **167** **168** **169** **170** **171**

Singlet Triplet Triplet

above), the mechanism is different from that of the di-π-methane rearrangement, because irradiation of a ketone can cause an $n \rightarrow \pi^*$ transition, which is of course not possible for a diene lacking a carbonyl group. The mechanism[861] in this case has been formulated as proceeding through the excited triplet states **168** and **169**. In step 1, the molecule undergoes an $n \rightarrow \pi^*$ excitation to the singlet species **167**, which cross to the triplet **168**. Step 3 is a rearrangement from one excited state to another. Step 4 is a $\pi^* \rightarrow n$ electron demotion (an intersystem crossing from $T_1 \rightarrow S_0$, see p. 339). The conversion of **170** to **171** consists of two 1,2 alkyl migrations (a one-step process would be a 1,3-migration of alkyl to a carbocation center, see p. $$$): The old C_6–C_5 bond becomes the new C_6–C_4 bond and the old C_6–C_1 bond becomes the new C_6–C_5 bond.[862]

2,4-Cyclohexadienones also undergo photochemical rearrangements, but the products are different, generally involving ring opening.[863]

[860]For reviews of the photochemistry of 2,5-cyclohexadienones and related compounds, see Schaffner, K.; Demuth, M., in de Mayo, P. *Rearrangements in Ground and Excited States*, Vol. 3, Academic Press, NY, ***1980***, pp. 281–348; Zimmerman, H.E. *Angew. 18-40 The Hofmann–Löffler and Related Reactions

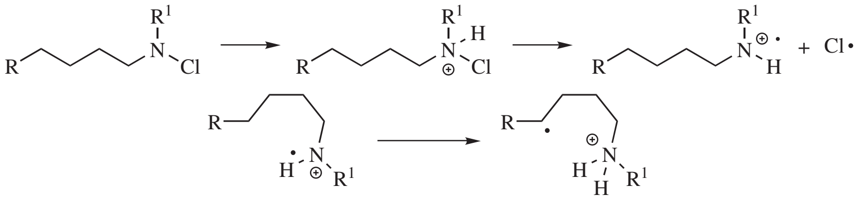
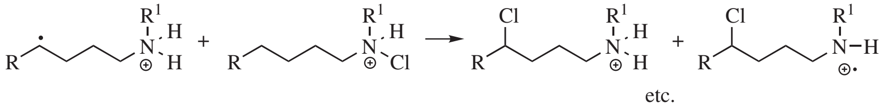
A common feature of the reactions in this section[864] is that they serve to introduce functionality at a position remote from functional groups already present. As such, they have proved very useful in synthesizing many compounds, especially in the steroid field (see also, **19-2** and **19-17**). When *N*-haloamines in which one alkyl group has a hydrogen in the 4 or 5 position are heated with sulfuric acid, pyrrolidines, or piperidines are formed, in a reaction known as the *Hofmann–Löffler reaction* (also called the *Hofmann–Löffler–Freytag reaction*).[865] The R′ group is normally alkyl, but the reaction has been extended to R′ = H by the use of concentrated sulfuric acid solution and ferrous salts.[866] The first step of the reaction is a rearrangement, with the halogen migrating from the nitrogen to the 4 or 5 position of the alkyl group. It is possible to isolate the resulting haloamine salt, but usually this is not done, and the second step, the ring closure (**10-31**), takes place. Though the reaction is most often induced by heat, this is not necessary, and irradiation and chemical initiators (e.g., peroxides) have been used instead. The mechanism is of a free-radical type, with the main step involving an internal hydrogen abstraction.[867]

Initiation



Propagation



etc.

A similar reaction has been carried out on *N*-halo amides, which give γ-lactones:[868]

[864]For a review of the reactions in this section, see Carruthers, W. *Some Modern Methods of Organic Synthesis* 3rd ed.; Cambridge University Press: Cambridge, ***1986***, pp. 263–279.

[865]For reviews, see Stella, L. *Angew. Chem. Int. Ed.* ***1983***, *22*, 337; Sosnovsky, G.; Rawlinson, D.J. *Adv. Free-Radical Chem.* ***1972***, *4*, 203, see pp. 249–259; Deno, N.C. *Methods Free-Radical Chem.* ***1972***, *3*, 135, see pp. 136–143.

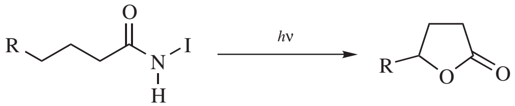
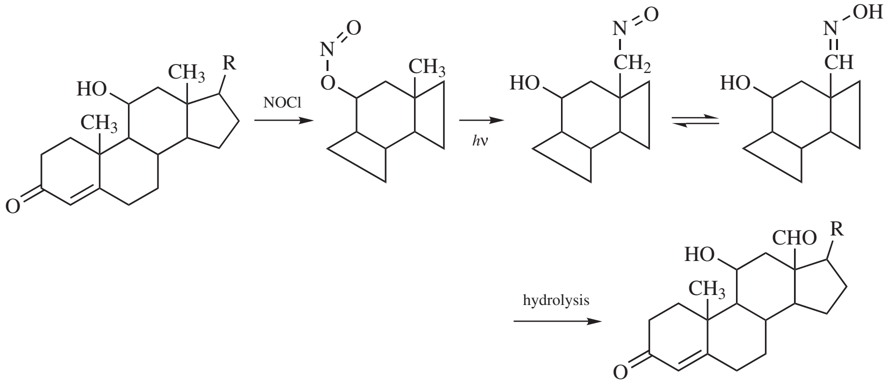
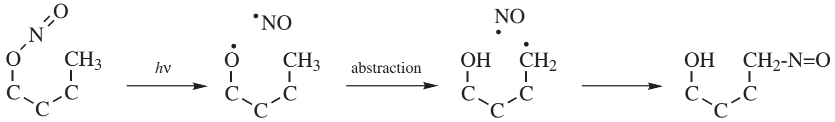
Soc.* ***1964***, *86*, 1648; Neale, R.S.; Marcus, N.L.; Schepers, R.G. *J. Am. Chem. Soc.* ***1966***, *88*, 3051. For a review of *N*-halo amide rearrangements, see Neale, R.S. *Synthesis* ***1971***, 1.



Another related reaction is the *Barton reaction*,[869] by which a methyl group in the ∂ position to an OH group can be oxidized to a CHO group. The alcohol is first converted to the nitrite ester. Photolysis of the nitrite results in conversion of the nitrite group to the OH group and nitrosation of the methyl group. Hydrolysis of the oxime tautomer gives the aldehyde, for example,[870]



This reaction takes place only when the methyl group is in a favorable steric position.[871] The mechanism is similar to that of the Hofmann–Löffler reaction.[872]



[869]For reviews, see Hesse, R.H. *Adv. Free-Radical Chem.* ***1969***, *3*, 83; Barton, D.H.R. *Pure Appl. Chem.* ***1968***, *16*, 1.

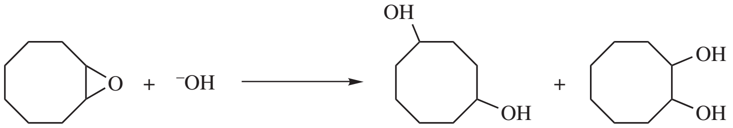
See also, Nickon, A.; Ferguson, R.; Bosch, A.; Iwadare, T. *J. Am. Chem. Soc.* ***1977***, *99*, 4518; Barton, D.H.R.; Hesse, R.H.; Pechet, M.M.; Smith, L.C. *J. Chem. Soc. Perkin Trans. 1* ***1979***, 1159; Green, M.M.; Boyle, B.A.; Vairamani, M.; Mukhopadhyay, T.; Saunders, Jr., W.H.; Bowen, P.; Allinger, N.L. *J. Am. Chem. Soc.* ***1986***, *108*, 2381.

This is one of the few known methods for effecting substitution at an angular methyl group. Not only CH_3 groups, but also alkyl groups of the form RCH_2 and R_2CH can give the Barton reaction if the geometry of the system is favorable. An RCH_2 group is converted to the oxime R(C=NOH) (which is hydrolyzable to a ketone) or to a nitroso dimer, while an R_2CH group gives a nitroso compound $R_2C(NO)$. With very few exceptions, the only carbons that become nitrosated are those in the position δ to the original OH group, indicating that a six-membered transition state is necessary for the hydrogen abstraction.[873]

OS **III**, 159.

D. Noncyclic Rearrangements

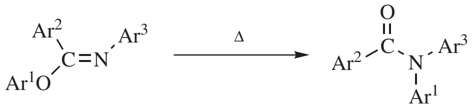
18-41 Hydride Shifts



The above is a typical example of a transannular hydride shift. The 1,2-diol is formed by a normal epoxide hydrolysis reaction (**10-7**). For a discussion of 1,3 and longer hydride shifts (see p. 1572).

18-42 The Chapman Rearrangement

1/*O* → 3/*N*-Aryl-migration



In the *Chapman rearrangement*, *N,N*-diaryl amides are formed when aryl imino esters are heated.[874] Best yields are obtained in refluxing tetraethylene glycol dimethyl ether (tetraglyme),[875] although the reaction can also be carried out without any solvent at all. Many groups may be present in the rings, for example, alkyl, halo, OR, CN, and COOR. Aryl migrates best when it contains electron-withdrawing groups. On the other hand, electron-withdrawing groups in Ar^2 or Ar^3 decrease the reactivity. The products can be hydrolyzed to diarylamines, and

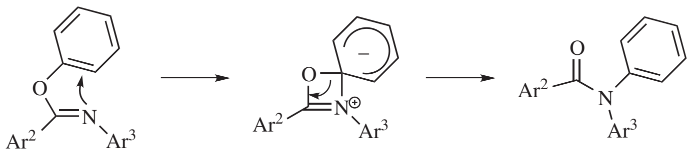
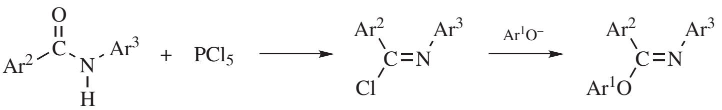
[875]Wheeler, O.H.; Roman, F.; Santiago, M.V.; Quiles, F. *Can. J. Chem.* ***1969***, *47*, 503.

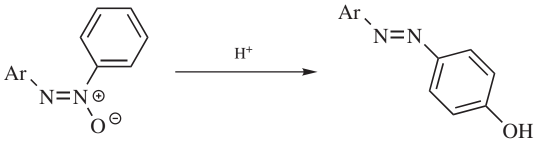


this is a method for preparing these compounds. The mechanism probably involves an intramolecular[876] aromatic nucleophilic substitution, resulting in a 1,3 oxygen-to-nitrogen shift. Aryl imino esters can be prepared from *N*-aryl amides by reaction with PCl_5, followed by treatment of the resulting imino chloride with an aroxide ion.[877]



Imino esters with any or all of the three groups being alkyl also rearrange, but they require catalysis by H_2SO_4 or a trace of methyl iodide or methyl sulfate.[878] The mechanism is different, involving an intermolecular process.[879] This is also true for derivatives for formamide (Ar^2 = H).

18-43 The Wallach Rearrangement



172 **173**

The conversion of azoxy compounds, on acid treatment, to *p*-hydroxy azo compounds (or sometimes the *o*-hydroxy isomers[880]) is called the *Wallach rearrangement*.[881] When both para positions are occupied, the *o*-hydroxy product may be

[876]For evidence for the intramolecular character of the reaction, see Wiberg, K.B.; Rowland, B.I. *J. Am. Chem. Soc.* ***1955***, *77*, 2205; Wheeler, O.H.; Roman, F.; Rosado, O. *J. Org. Chem.* ***1969***, *34*, 966; Kimura, M. *J. Chem. Soc. Perkin Trans. 2* ***1987***, 205.

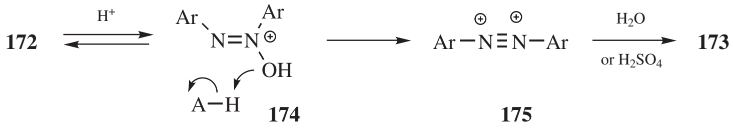
obtained, but ipso substitution at one of the para positions is also possible.[882] Although the mechanism[883] is not completely settled, the following facts are known: (*1*) The para rearrangement is intermolecular.[884] (*2*) When the reaction was carried out with an azoxy compound in which the N–O nitrogen was labeled with ^{15}N, *both* nitrogens of the product carried the label equally,[885] demonstrating that the oxygen did not have a preference for migration to either the near or the far ring. This shows that there is a symmetrical intermediate. (*3*) Kinetic studies show that two protons are normally required for the reaction.[886] The following mechanism,[887] involving the symmetrical intermediate **175**, has been proposed to explain the facts.[888]



It has proved possible to obtain **174** and **175** as stable species in super acid solutions.[748] Another mechanism, involving an intermediate with only one positive charge, has been proposed for certain substrates at low acidities.[889]

A photochemical Wallach rearrangement[890] is also known: The product is the *o*-hydroxy azo compound, the OH group is found in the farther ring, and the rearrangement is intramolecular.[891]

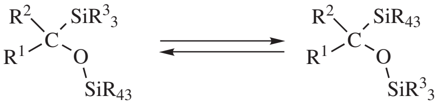
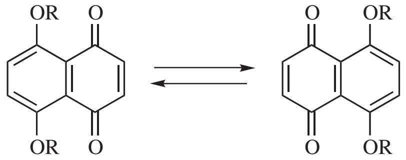
18-44 Dyotropic Rearrangements

1/*C*-Trialkylsilyl,2/*O*-trialkylsilyl-interchange



A *dyotropic rearrangement*[892] is an uncatalyzed process in which two σ bonds simultaneously migrate intramolecularly.[893] There are two types. The above is an example of type 1, which consists of reactions in which the two σ bonds interchange positions. In type 2, the two σ bonds do not interchange positions. An example is



Some other examples are

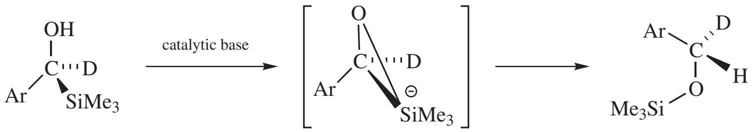
(α-hydroxybenzyl)trialkylsilanes (**176**) in the presence of a catalytic amount of base.[898] Formation of a Si–O bond rather than the Si–C bond drives the rearrangement, which is believed to proceed via formation of **177**, and does proceed with inversion of configuration at carbon and retention of configuration at silicon.[899] A reverse Brook rearrangement is also known.[900] The reaction has been extended to other systems. A homo-Brook rearrangement has also been reported.[901] Another variation is the aza-Brook rearrangement of α-silylallyl)amines.[902] The Brook rearrangement has been used in synthesis involving silyl dithianes.[903] A Brook rearrangement mediated [6 + 2]-annulation has been used for the construction of eight-membered carbocycles.[904]



176 **177**

The Brook rearrangement has been used in two important synthetic applications, a multicomponent coupling protocol initiated by a Brook rearrangement involving silyl dithianes as mentioned, and anion relay chemistry (ARC) involving a Brook rearrangement. An example of the former is the conversion of the 2-silyl dithiane **178** to the anion with *tert*-butyllithium followed by ring opening of an epoxide to give **179**.[905] Treatment with HMPA triggers a solvent-controlled Brook rearrangement that gives a new dithiane anion (**180**), which then reacts with a different epoxide to give the final product, **181**. An example of the anion relay chemistry treats dithiane (**182**) with *n*-butyllithium, and then **183** to give **184**.[906] Subsequent treatment with a variety of electrophiles, such as allyl bromide, in HMPA, leads to **185** via a Brook rearrangement, and then alkylation of the resultant dithian anion. This reaction can be initiated by nucleophiles other

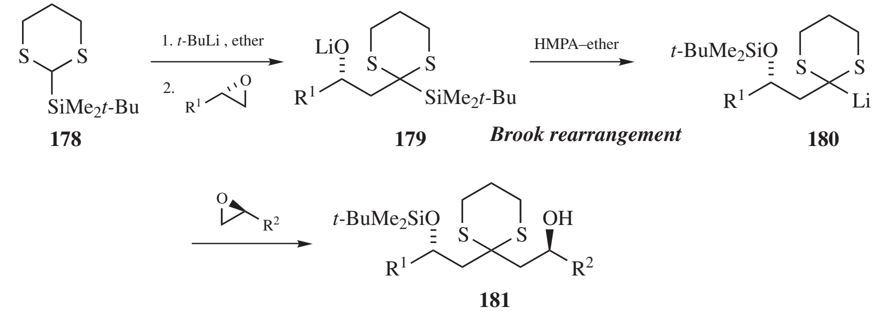
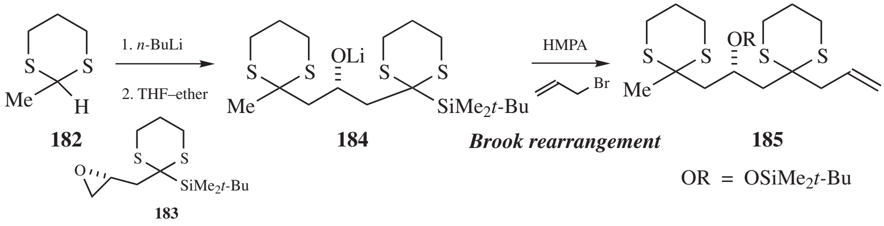
than dithiane anion. Organocuprates can be used, and the anion stabilizing group can be a nitrile.[907]





[907]Private communication, Professor Amos B. Smith III, University Pennsylvania.

CHAPTER 19

Oxidations and Reductions

First, we must examine what we mean when we speak of oxidation and reduction. Inorganic chemists define oxidation in two ways: loss of electrons and increase in oxidation number. In organic chemistry, these definitions, while still technically correct, are not easy to apply. While electrons are directly transferred in some organic oxidations and reductions, the mechanisms of most of these reactions do not involve a direct electron transfer. As for oxidation number, while this is easy to apply in some cases, (e.g., the oxidation number of carbon in CH_4 is -4), in most cases attempts to apply the concept lead to fractional values or to apparent absurdities. Thus carbon in propane has an oxidation number of -2.67 and in butane of -2.5, although organic chemists seldom think of these two compounds as being in different oxidation states. An improvement could be made by assigning different oxidation states to different carbon atoms in a molecule, depending on what is bonded to them (e.g., the two carbons in acetic acid are obviously in different oxidation states), but for this a whole set of arbitrary assumptions would be required, since the oxidation number of an atom in a molecule is assigned on the basis of the oxidation numbers of the atoms attached to it. There would seem little to be gained by such a procedure. The practice in organic chemistry has been to set up a series of functional groups, in a qualitative way, arranged in order of increasing oxidation state, and then to define oxidation as *the conversion of a functional group in a molecule from one category to a higher one*. Reduction is the opposite. For the simple functional groups this series is shown in Table 19.1.[1] Note that this classification applies only to a single carbon atom or to two adjacent carbon atoms. Thus 1,3-dichloropropane is in the same oxidation state as chloromethane, but 1,2-dichloropropane is in a higher one. Obviously, such distinctions are somewhat arbitrary, and if we attempt to carry them too far, we will find ourselves painted into a corner. Nevertheless, the basic idea has served organic chemistry well. Note that

[1]For more extensive tables, with subclassifications, see Soloveichik, S.; Krakauer, H. *J. Chem. Educ.* ***1966***, *43*, 532.

−4	−2	0	+2	+4

[a]Oxidation is the conversion of a functional group in a molecule to a higher category; reduction is conversion to a lower one. Conversions within a category are neither oxidations nor reductions. The numbers given at the bottom are only approximations.

conversion of any compound to another in the same category is not an oxidation or a reduction. Most oxidations in organic chemistry involve a gain of oxygen and/or a loss of hydrogen (Lavoisier's original definition of oxidation). The reverse is true for reductions.

Of course, there is no oxidation without a concurrent reduction. However, we classify reactions as oxidations or reductions depending on whether the *organic compound* is oxidized or reduced. In some cases, both the oxidant and reductant are organic; those reactions are treated separately at the end of the chapter.

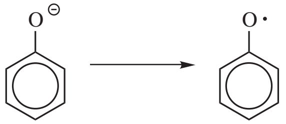
MECHANISMS

Noted that our definition of oxidation has nothing to do with mechanism. Thus the conversion of bromomethane to methanol with KOH (**10-1**) and to methane with $LiAlH_4$ (**19-53**) have the same S_N2 mechanisms, but one is a reduction (according to our definition) and the other is not. It is impractical to consider the mechanisms

of oxidation and reduction reactions in broad categories in this chapter as we have done for the reactions considered in Chapters 10–18.[2] The main reason is that the mechanisms are too diverse, and this in turn is because the bond changes are too different. For example, in Chapter 15, most reactions involved the bond change C=C → W—C—C—Y yet a relatively few mechanisms covered those reactions. But for oxidations and reductions the bond changes are far more diverse. Another reason is that the mechanism of a given oxidation or reduction reaction can vary greatly with the oxidizing or reducing agent employed. Very often the mechanism has been studied intensively for only one or a few of many possible agents.

Although we do not cover oxidation and reduction mechanisms in the same way as we have covered other mechanisms, it is still possible to list a few broad mechanistic categories. In doing this, we follow the scheme of Wiberg.[3]

1. *Direct Electron Transfer.*[4] We have already met some reactions in which the reduction is a direct gain of electrons or the oxidation a direct loss of them. An example is the Birch reduction (**15-13**), where sodium directly transfers an electron to an aromatic ring. An example from this chapter is found in the bimolecular reduction of ketones (**19-76**), where again it is a metal that supplies the electrons. This kind of mechanism is found largely in three types of reaction:[5] (a) the oxidation or reduction of a free radical (oxidation to a positive or reduction to a negative ion), (b) the oxidation of a negative ion or the reduction of a positive ion to a comparatively stable free radical, and (c) electrolytic oxidations or reductions (an example is the Kolbe reaction, **14-29**). An important example of (b) is oxidation of amines and phenolate ions:



[2]For monographs on oxidation mechanisms, see Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 16, Elsevier, NY, ***1980***; *Oxidation in Organic Chemistry*, Academic Press, NY, pt. Chem.* ***1982***, *18*, 79. For a review of multistage electron-transfer mechanisms, see Deuchert, K.; Hünig, S. *Angew. Chem. Int. Ed.* ***1978***, *17*, 875.

[5]Littler, J.S.; Sayce, I.G. *J. Chem. Soc.* ***1964***, 2545.

These reactions occur easily because of the relative stability of the radicals involved.[6] The single electron-transfer mechanism (SET), which we have met several times (e.g., p. 264) is an important case.

2. *Hydride Transfer.*[7] In some reactions, a hydride ion is transferred to or from the substrate. The reduction of epoxides with $LiAlH_4$ is an example (**19-35**). Another is the Cannizzaro reaction (**19-81**). Reactions in which a carbocation abstracts a hydride ion belong in this category:[8]

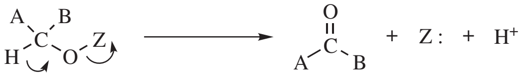
$$R^{+} + R'H \longrightarrow RH + R'^{+}$$

3. *Hydrogen-Atom Transfer.* Many oxidation and reduction reactions are free-radical substitutions and involve the transfer of a hydrogen atom. For example, one of the two main propagation steps of **14-1** involves abstraction of hydrogen:

$$RH + Cl\bullet \longrightarrow R\bullet + HCl$$

This is the case for many of the reactions of Chapter 14.

4. *Formation of Ester Intermediates.* A number of oxidations involve the formation of an ester intermediate (usually of an inorganic acid), and then the cleavage of this intermediate:



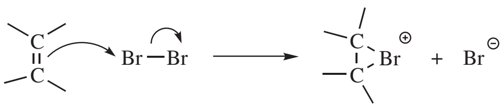
Z is usually CrO_3H, MnO_3, or a similar inorganic acid moiety. One example of this mechanism will be seen in **19-23**, where A was an alkyl or aryl group, B was OH, and Z was CrO_3H. Another is the oxidation of a secondary alcohol to a ketone (**19-3**), where A and B are alkyl or aryl groups and Z is also CrO_3H. In the lead tetraacetate oxidation of glycols (**19-7**) the mechanism also follows this pattern, but the positive leaving group is carbon instead of hydrogen. Note that the cleavage shown is an example of an E2 elimination.

5. *Displacement Mechanisms.* In these reactions, the organic substrate uses its electrons to cause displacement on an electrophilic oxidizing agent. One example is the addition of bromine to an alkene (**15-39**).

[6]For a review of the oxidation of phenols, see Mihailović, M.Lj.; Čeković, Z., in Patai, S. *The Chemistry of the Hydroxyl Group*, pt. 1, Wiley, NY, ***1971***, pp. 505–592.

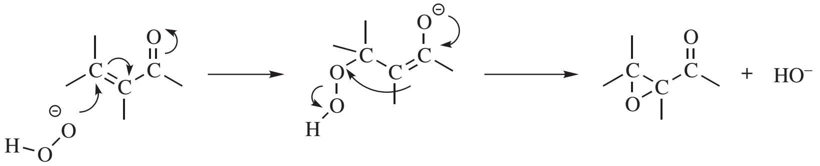
[7]For a review, see Watt, C.I.F. *Adv. Phys. Org. Chem.* ***1988***, *24*, 57.

[8]For a review of these reactions, see Nenitzescu, C.D., in Olah, G.A.; Schleyer, P.V.R. *Carbonium Ions*, Vol. 2, Wiley, NY, ***1970***, pp. 463–520.



An example from this chapter is found in **19-29**:

6. *Addition–Elimination Mechanisms*. In the reaction between α,β-unsaturated ketones and alkaline peroxide (**15-50**), the oxidizing agent adds to the substrate and then part of it is lost:



In this case, the oxygen of the oxidizing agent is in oxidation state −1 and the hydroxide ion departs with its oxygen in the −2 state, so it is reduced and the substrate oxidized. There are several reactions that follow this pattern of addition of an oxidizing agent and the loss of part of the agent, usually in a different oxidation state. Another example is the oxidation of ketones with SeO_2 (**19-17**). This reaction is also an example of category 4, since it involves formation and E2 cleavage of an ester. This example shows that these six categories are not mutually exclusive.

REACTIONS

In this chapter, the reactions are classified by the type of bond change occurring to the organic substrate, in conformity with our practice in the other chapters.[9] This means that there is no discussion in any one place of the use of a particular oxidizing or reducing agent, for example, acid dichromate or $LiAlH_4$ (except for a discussion of selectivity of reducing agents, p. 1787). Some oxidizing or reducing agents are fairly specific in their action, attacking only one or a few types of substrate.

[9]For a table of oxidation and reduction reactions, and the oxidizing and reducing agents for each, see Hudlický, M. *J. Chem. Educ.* ***1977***, *54*, 100.

Others, like acid dichromate, permanganate, $LiAlH_4$, and catalytic hydrogenation, are much more versatile.[10,9,11]

OXIDATIONS[11,2]

In some cases, oxidations have been placed in another chapter. The oxidation of an alkene to a diol (**15-48**), and aromatic compound to a diol (**15-49**), or oxidation to an epoxide (**15-50**) are placed in Chapter 15, for consistency with the concept of addition to a π-bond. Diamination of an alkene (**15-53**) and formation of aziridines (**15-54**) are in Chapter 15 for the same reason. Most other oxidations have been placed here. The reactions in this section are classified into groups depending on

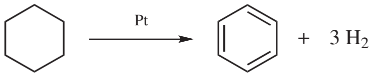
the type of bond change involved. These groups are (A) eliminations of hydrogen, (B) oxidations involving cleavage of carbon–carbon bonds, (C) reactions involving replacement of hydrogen by oxygen, (D) reactions in which oxygen is added to the substrate, and (E) oxidative coupling.

A. Eliminations of Hydrogen

19-1 Aromatization of Six-Membered Rings

Hexahydro-terelimination



Six-membered alicyclic rings can be aromatized in a number of ways.[12] Aromatization is accomplished most easily if there are already one or two double bonds in the ring or if the ring is fused to an aromatic ring. The reaction can also be applied to heterocyclic five - and six-membered rings. Many groups may be present on the ring without interference, and even *gem*-dialkyl substitution does not always prevent the reaction: In such cases, one alkyl group often migrates or is eliminated. However, more drastic conditions are usually required for this. In some cases OH and COOH groups are lost from the ring. Cyclic ketones are converted to phenols. Seven-membered and larger rings are often isomerized to six-membered aromatic rings, although this is not the case for partially hydrogenated azulene systems (which are frequently found in Nature); these are converted to azulenes.

There are three types of reagents most frequently used to effect aromatization.

1. Hydrogenation catalysts,[13] such as platinum, palladium,[14] and nickel. In this case, the reaction is the reverse of double-bond hydrogenation (**15-11** and **15-15**), and presumably the mechanism is also the reverse, although not much is known.[15] Cyclohexene has been detected as an intermediate in the conversion of cyclohexane to benzene, using Pt.[16] The substrate is heated with the catalyst at ~ 300–350°C. The reactions can often be carried out under milder

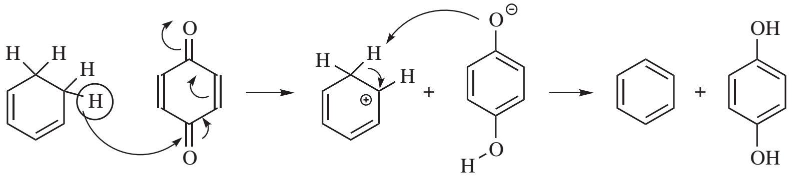
conditions if a hydrogen acceptor, such as maleic acid, cyclohexene, or benzene, is present to remove hydrogen as it is formed. The acceptor is reduced to the saturated compound. Other transition metals can be used, including $TiCl_4$-NEt_3.[17] It has been reported that dehydrogenation of 1-methylcyclohexene-1-^{13}C over an alumina catalyst gave toluene with the label partially scrambled throughout the aromatic ring.[18] For polycylic systems, heating with oxygen on activated carbon generates the aromatic compound, as in the conversion of dihydroanthracene to anthracene.[19]

2. The elements sulfur and selenium, which combine with the hydrogen evolved to give, respectively, H_2S and H_2Se. Little is known about this mechanism either.[20]
3. Quinones,[21] which become reduced to the corresponding hydroquinones. Two important quinones often used for aromatizations are chloranil (2,3,5,6-tetrachloro-1,4-benzoquinone) and DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone).[22] The latter is more reactive and can be used in cases where the substrate is difficult to dehydrogenate. It is likely that the mechanism involves a transfer of hydride to the quinone oxygen, followed by the transfer of a proton to the phenolate ion:[23,21]



Among other reagents[24] that have been used for aromatization of six-membered rings are atmospheric oxygen, MnO_2,[25] $KMnO_4$-Al_2O_3,[26] SeO_2, various strong bases,[27]

chromic acid,[28] H_2SO_4 and a ruthenium catalyst,[29] and SeO_2 on $P_2O_5/Me_3SiOSiMe_3$.[30] The last-mentioned reagent also dehydrogenates cyclopentanes to cyclopentadienes. In some instances, the hydrogen is not released as H_2 or transferred to an external oxidizing agent, but instead serves to reduce another molecule of substrate. This is a disproportionation reaction and can be illustrated by the conversion of cyclohexene to cyclohexane and benzene. Quinones react with allylic silanes and a $Bi(OTf)_3$ catalyst to give 2-allyl hydroquinone.[31] Similar reaction with acetic anhydride rather than an allylic silane leads to a 2-acetoxy hydroquinone.[32]

Heteroatom rings, as found in quinoline derivatives, for example, can be generated from amino-ketones with [hydroxy(tosyloxy)iodo]benzene and perchloric acid[33] or with $NaHSO_4$—$Na_2Cr_2O_7$ on wet silica.[34] Dihydropyridines are converted to pyridines with $NaNO_2$–oxalic acid and wet silica[35] $BaMnO_4$,[36] $FeCl_3$–acetic acid,[37] $Mg(HSO_4)_2$—$NaNO_2$,[38] NO^+-18-crown-6-$H(NO_3)_2^-$,[39] or with nicotinium dichromate.[40] Cyclic imines are converted to pyridine derivatives with NCS, and then excess sodium methoxide.[41]

Note that hydrogenolysis of cyclohexane leads to *n*-hexane with hydrogen and an iridium catalyst.[42]

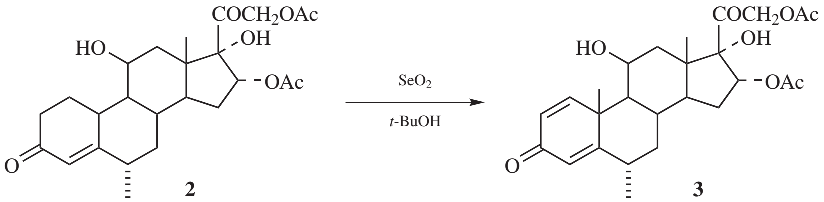
Dehydrogenation of an aliphatic compound to give a double bond in a specific location is not usually a feasible process, although industrially mixtures of alkenes are obtained in this way from mixtures of alkanes (generally by heating with chromia–alumina catalysts). There are, however, some notable exceptions. Heating cyclooctane with an iridium catalyst leads to cyclooctene.[43] Treating alkenes that have an allylic hydrogen with $CrCl_2$ converts them to allenes.[44] It is not surprising, however, that most of the exceptions generally involve cases where the new double bond can be in conjugation with a double bond or with an unshared pair of electrons already present.[45] One example is the synthesis developed by Leonard and co-workers,[46] in which tertiary amines give enamines (**10-69**) when treated with mercuric acetate[47] (see the example above). In this case the initial product is the iminium ion **1** which loses a proton to give the enamine. In another example, the oxidizing agent SeO_2 can in certain cases convert a carbonyl compound to an α,β-unsaturated carbonyl compound by removing H_2[48] (though this reagent more often gives **19-17**). This reaction has been most often applied in the steroid series, an example being formation of **2** from **3**.[49] In a similar manner, Hünig's base, diisopropylethylamine, was converted to the enamine *N,N*-diisopropyl-*N*-vinylamine by heating with an iridium catalyst.[50]



2 **3**

Similarly, SeO_2 has been used to dehydrogenate 1,4-diketones[51] ($RCOCH_2CH_2$-$COR \rightarrow RCOCH{=}CHCOR$) and 1,2-diarylalkanes ($ArCH_2CH_2Ar \rightarrow ArCH{=}CHAr$). These conversions can also be carried out by certain quinones, most notably DDQ (see **19-1**).[22] Ketones have been converted to conjugated ketones with

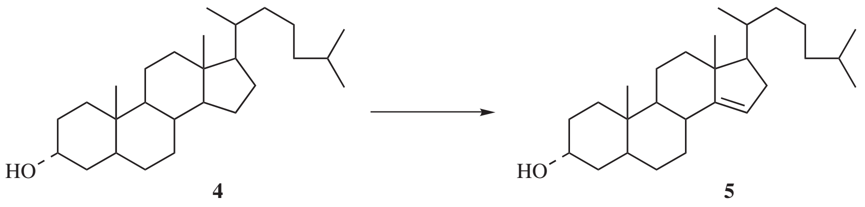
Ph(S=O)OMe and KH,[52] and also with (pyridyl)S(=O)OMe/KH, and then $CuSO_4$.[53] Silyl enol ethers also give the conjugated ketone upon treatment with ceric ammonium nitrate in DMF[54] or with $Pd(OAc)_2/NaOAc/O_2$.[55] Simple aldehydes and ketones have been dehydrogenated (e.g., cyclopentanone → cyclopentenone) by $PdCl_2$,[56] by $FeCl_3$,[57] and by benzeneseleninic anhydride[58] (this reagent also dehydrogenates lactones in a similar manner), among other reagents.

In an indirect method of achieving this conversion, the silyl enol ether of a simple ketone is treated with DDQ[59] or with triphenylmethyl cation[60] (for another indirect method, see **17-12**). Simple linear alkanes have been converted to alkenes by treatment with certain transition-metal compounds.[61]



An entirely different approach to specific dehydrogenation has been reported by R. Breslow[62] and by J.E. Baldwin.[63] By means of this approach it was possible, for example, to convert 3α-cholestanol (**4**) to 5α-cholest-14-en-3α-ol (**5**), thus introducing a double bond at a specific site remote from any functional group.[64] This was

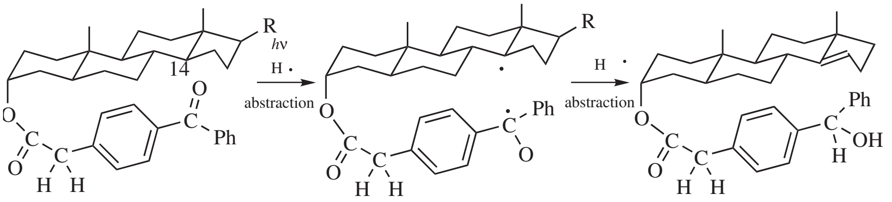
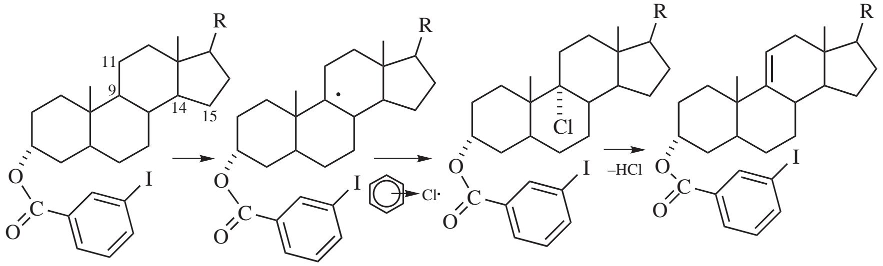
accomplished by conversion of **4** to the ester **6**, followed by irradiation of **6**, which gave 55% **8**, which was then



6 **7** **8**

hydrolyzed to **5**. The radiation excites the benzophenone portion of **6** (p. $$$), which then abstracts hydrogen from the 14 position to give the diradical **7**, which undergoes another internal abstraction to give **8**. In other cases, diradicals like **7** can close to a macrocyclic lactone (**19-17**). In an alternate approach,[65] a 9(11) double bond was introduced into a steroid nucleus by reaction of the *m*-iodo ester **9** with $PhICl_2$ and uv light, which results in hydrogen being abstracted regioselectively from the 9 position, resulting in chlorination at that position. Dehydrohalogenation of **10** gives the 9(11)-unsaturated steroid **11**. In contrast, use of the para isomer of **7** results in chlorination at the 14 position and loss of HCl gives the 14-unsaturated steroid. These reactions are among the very few ways to introduce functionality at a specific site remote from any functional group (see also, **19-17**).



9 **10** **11**

Certain 1,2-diarylalkenes ArCH=CHAr' have been converted to the corresponding alkynes ArC≡CAr' by treatment with *t*-BuOK in DMF.[66] Dihydroindoles are converted to indoles with *N,N′,N″*-trichloro-1,3,5-triazin-2,4,6-trione and DBU.[67]

other strong oxidizing agents ($KMnO_4$,[72] ruthenium tetroxide,[73] etc.) have also been employed. A solution of chromic acid and sulfuric acid in water is known as the *Jones reagent*.[74] When secondary alcohols are dissolved in acetone, titration with the Jones reagent oxidizes them to ketones rapidly and in high yield without disturbing any double or triple bonds that may be present (see **19-10**) and without epimerizing an adjacent stereogenic center.[75] The Jones reagent can also oxidize primary allylic alcohols to the corresponding aldehydes,[76] although overoxidation to the carboxylic acid is a problem. Oxidative cleavage of primary alcohols has been observed in the presence of molecular sieve 3 Å.[77] Indeed, for the oxidation of allylic alcohols three other Cr(VI) reagents are commonly used,[78] dipyridine Cr(VI) oxide (*Collins' reagent*),[79] pyridinium chlorochromate (PCC),[80] and pyridinium dichromate (PDC).[81] The PCC is somewhat acidic, and acid-catalyzed rearrangements have been observed.[82] A variety of amines and diamines have been converted to tetraalkylammonium halochromates or dichromates. Examples include *N*-benzyl 1,4-diazabicyclo[2.2.2]octane ammonium dichromate with microwave irradiation,[83] γ-picolinium chlorochromate,[84] and quinolinium

fluorochromate.[85] benzyltriphenylphosphonium chlorochromate has been used in a similar manner.[86] Ammonium dichromate with HIO_3 on wet silica gel[87] or ammonium chlorochromate on Montmorillonite K10[88] have also been used. The MnO_2[89] reagent is also a fairly specific reagent for oxidation of allylic and benzylic OH groups in preference to aliphatic substrates. For acid-sensitive compounds, CrO_3 in HMPA[90] or trimethylsilyl chromates[91] can be used. Benzylic alcohols are oxidized to aldehydes with $BaCr_2O_7$ in acetonitrile.[92] Both CrO_3[93] and MnO_2[94] have been used to oxidized primary and benzylic alcohols, respectively, under solvent-free conditions. A catalytic mixture of *N*-hydroxyphthalimide, $Co(OAc)_2$ and mcpba oxidizes secondary alcohols to ketones.[95] Chromium trioxide with aqueous *tert*-butylhydroperoxide oxidizes benzylic alcohols with microwave irradiation.[96] Oxidizing agents have been supported on a polymer,[97] including chromic acid[98] and permanganate,[99] as well as poly[vinyl(pyridinium fluorochromate)].[100] Microwave induced oxidation of benzylic alcohols was reported using zeolite-supported ferric nitrate.[101] Microwave irradiation of CrO_3 with various co-reagents oxidizes alcohols.[102] Phase-transfer catalysis has also been used with permanganate,[103] chromic acid,[104] and

ruthenium tetroxide.[105] Phase-transfer catalysis is particularly useful because the oxidizing agents are insoluble in most organic solvents, while the substrates are generally insoluble in water (see p. 508). Ultrasound has been used for $KMnO_4$ oxidations.[106] A catalytic amount of $Cr(acac)_3$ in conjunction with H_5IO_5 oxidizes benzylic alcohols to aldehydes.[107]

Most of these oxidizing agents have also been used to convert primary alcohols to aldehydes, but precautions must be taken that the aldehyde is not further oxidized to the carboxylic acid (**19-22**).[108] When powerful oxidants, such as chromic acid, are used, one way to halt oxidation is by distillation of the aldehyde as it is formed. The following are among the oxidizing agents that have been used to convert at least some primary alcohols to aldehydes:[109] Collins' reagent, pyridinium chlorochromate and pyridinium dichromate, pyridinium dichromate, $Na_2Cr_2O_7$ in water,[110] $K_2Cr_2O_7$ in DMF at 100°C,[111] CrO_3 on silica gel,[112] wet CrO_3 on alumina with microwave irradiation,[113] $MeReO_3$,[114] HNO_3 with a $Yb(OTf)_3$ catalyst,[115] $FeBr_3$-H_2O_2,[116] a catalytic amount of $AuSiO_2$,[117] cerium (IV) immobilized on silica with $NaBrO_3$,[118] a bismuth catalyst,[119] O_2 with transition metal

[108]Though ketones are much less susceptible to further oxidation than aldehydes, such oxidation is possible (**19-8**), and care must be taken to avoid it, usually by controlling the temperature and/or the oxidizing agent.

catalysts,[120] RuO_2 with a zeolite catalyst,[121] and CuCl–phenanthroline.[122]

Tetrapropylammonium perruthenate (Pr_4N^+ RuO_4^-; also called TPAP; the *Ley reagent*)[123] has become an important oxidizing agent. This reagent has been bound to a polymer.[124] In the presence of molecular oxygen, it is catalytic in TPAP.[125] A polymer-bound morpholine *N*-oxide has been used in conjunction with a catalytic amount of TPAP.[126] Propargylic alcohols are oxidized to propargylic aldehydes with $TiCl_4/NEt_3$.[127] Methods have been developed for recovery of the catalyst and reuse of TPAP.[128]

Most of these reagents also oxidize secondary alcohols to ketones. Reagents that can be used specifically to oxidize a secondary OH group in the presence of a primary OH group[129] are H_2O_2–ammonium molybdate,[130] $NaBrO_3$–CAN,[131] and NaOCl in HOAc,[132] while $RuCl_2(PPh_3)_3$–benzene,[133]

osmium tetroxide,[134] and $Br_2Ni(OBz)_2$[135] oxidize primary OH groups in the presence of a secondary OH group.[136] Benzylic and allylic alcohols have been selectively oxidized to the aldehydes in the presence of saturated alcohols by the use of potassium manganate $KMnO_4$ under phase-transfer conditions.[137] On the other hand, Fremy's salt (see **19-4**) selectively oxidizes benzylic alcohols and not allylic or saturated ones.[138] Certain zirconocene complexes can selectively oxidize only one OH group of a diol, even if both are primary.[139] α-Hydroxy ketones are oxidized to 1,2-diketones with $Bi(NO_3)_3$ and a $Cu(OAc)_2$ catalyst,[140] ferric chloride (solid state),[141] or O_2 and a vanadium catalyst.[142] Tetrabutylammonium periodate oxidizes primary alcohols to aldehydes,[143] as does benzyltriphenylphosphonium periodate.[144] α-Hydroxyl phosphonate esters are oxidized to the α-keto phosphonate ester with zinc dichromate, without solvent[145] or with CrO_3 on alumina with microwave irradiation.[146]

O-Trimethylsilyl ethers of benzylic alcohols are oxidized to the corresponding aldehyde with CrO_3 on wet alumina.[147] Treatment with $MnO_2/AlCl_3$ leads to similar oxidation,[148] as does $NaBrO_3$ in aq. MeCN[149] or K_2FeO_4 on clay.[150] Oxidation of trimethylsilyl ethers with O_2, a catalytic amount of *N*-hydroxyphthalimide and a cobalt catalyst give an aldehyde.[151] Microwave irradiation with $BiCl_3$ oxidizes benzylic TMS ethers to the aldehyde.[152] Microwave irradiation on zeolite supported ferric nitrate has been used.[153] *O*-Tetrahydropyranyl ethers (*O*-THP) have been oxidized to the aldehyde with ferric nitrate on zeolites.[154]

2. *The Oppenauer Oxidation*. When a ketone in the presence of an aluminum alkoxide is used as the oxidizing agent (it is reduced to a secondary alcohol), the reaction is known as the *Oppenauer oxidation*.[155] This is the reverse of the Meerwein–Ponndorf–Verley reaction (**19-36**) and the mechanism is also the reverse. The ketones most commonly used are acetone, butanone, and cyclohexanone. The most common base is aluminum *tert*-butoxide. The chief advantage of the method is its high selectivity. Although the method is most often used for the preparation of ketones, it has also been used for aldehydes. An iridium catalyst[156] has been developed for the Oppenauer oxidation, and also a water-soluble iridium catalyst[157] An uncatalyzed reaction under supercritical conditions was reported.[158]
3. *With DMSO-Based Reagents*. An alcohol is treated with DMSO, DCC,[159] and anhydrous phosphoric acid[160] in what is called *Moffatt oxidation*. In this way, a primary alcohol can be converted to the aldehyde with no carboxylic acid being produced. The strong acid conditions are sometimes a problem, and complete removal of the dicyclohexylurea by-product can be difficult. The use of oxalyl chloride and DMSO at low temperature, the Swern oxidation,[161] is generally more practical and widely used. Maintaining the low reaction temperature is essential in this reaction however, since the reagent generated *in situ* decomposes at temperatures significantly below ambient.

   Similar oxidation of alcohols has been carried out with DMSO and other reagents[162] in place of DCC: acetic anhydride,[163] SO_3–pyridine–triethylamine,[164] trifluoroacetic anhydride,[165] tosyl chloride,[166] $Ph_3P^+Br^-$,[167]

[155]For a review, see Djerassi, C. *Org. React.* ***1951***, *6*, 207. For the use of new catalyst,s see Akamanchi, K.G.; Chaudhari, B.A. *Tetrahedron Lett.* ***1997***, *38*, 6925; Ooi, T.; Miura, T.; Itagaki, Y.; Ichikawa, H.; Maruoka, K. *Synthesis* ***2002***, 279.

[156]Suzuki, T.; Morita, K.; Tsuchida, M.; Hiroi, K. *J. Org. Chem.* ***2003***, *68*, 1601.

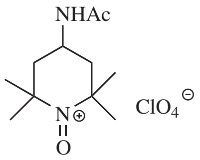
ionic liquid oxidizes benzylic alcohols to the corresponding aldehyde.[194] Other nitroxyl radical oxidizing agents are known.[195] A related oxidizing agent is oxoammonium salt **12** (*Bobbitt's reagent)*, a stable and nonhygroscopic salt that oxidizes primary and secondary alcohols in dichloromethane.[196]



12

5. *With Hypervalent Iodine Reagents.*[197] Treatment of 2-iodobenzoic acid with $KBrO_3$ in sulfuric acid and heating the resulting product to 100°C with acetic anhydride and acetic acid gives hypervalent iodine reagent **13**, the so-called *Dess–Martin Periodinane.*[198] This reagent reacts with alcohols at ambient temperature to give the corresponding aldehyde or ketone.[199] The reaction is accelerated by water[200] and a water-soluble periodinane (*o*-iodoxybenzoic acid, **14**) has been prepared that oxidized allylic alcohols to conjugated aldehydes.[201]

The reagent has an indefinite shelf-life in a sealed container, but hydrolysis occurs upon long-term exposure to atmospheric moisture. A note of CAUTION! The Dess–Martin reagent can be shock sensitive under some conditions and explode >200°C.[202] Other hypervalent iodine oxidizing reagents are known,[203] including $PhI(OAc)_2$/TEMPO,[204] $PhI(OAc)_2$–chromium salen,[205] stabilized iodoxybenzoic acid,[206] and $PhI(OAc)_2$ supported on alumina with microwave irradiation.[207] Microwave irradiation of benzylic alcohols with PhI(OH)OTs gave the corresponding aldehyde.[208] Hypervalent iodine compounds have been used in ionic liquids.[209] Heating benzylic alcohols with *o*-iodoxybenzoic acid under solvent-free conditions gave the aldehyde.[210] Cyclopropylcarbinyl alcohols are oxidized to the corresponding cyclopropyl ketone or aldehyde with PhIO and a chromium–salen catalyst.[211] The Dess–Martin reagent oxidized aryl aldoximes to aryl aldehydes.[212]

6. *By Catalytic Dehydrogenation*. For the conversion of primary alcohols to aldehydes, dehydrogenation catalysts have the advantage over strong oxidizing agents that further oxidation to the carboxylic acid is prevented. Copper chromite is the agent most often used, but other catalysts (e.g., silver and copper) have also been employed. Many ketones were prepared in this manner. Catalytic dehydrogenation is more often used industrially than as a laboratory method. However, procedures using copper oxide,[213] copper(II) complexes,[214] rhodium complexes,[215] ruthenium complexes,[216] Raney nickel,[217] and palladium complexes[218] (under phase-transfer conditions)[219]

have been reported. Allylic alcohols[220] are oxidized to the corresponding saturated aldehyde or ketone by heating with a rhodium catalyst, and benzylic alcohols are converted to the aldehyde with a rhodium catalyst.[221] Photolysis with an iron catalyst gives similar results.[222] Propargylic alcohols are oxidized by heating with a vanadium catalyst.[223] Secondary alcohols are oxidized with $Bi(NO_3)_3$ on Montmorillonite.[224]

7. *Miscellaneous Reagents*.[225] Nitric acid in dichloromethane oxidizes benzylic alcohols to the corresponding ketone. [226] Bromine is an effective oxidant, and iodine under photochemical conditions has been used.[227] Heating a 1,2-diol with NBS in CCl_4 gave the 1,2-diketone.[228] *N*-Bromosuccinimide with β-cyclodextrin oxidizes tetrahydropyranyl ethers in water.[229] Iodine has been used in conjunction with DMSO and hydrazine.[230] Sodium bromate (NaOBr) in conjunction with HCl oxidizes α-hydroxy esters to α-keto esters.[231] Enzymatic oxidations have been reported.[232] Dimethyl dioxirane[233] oxidizes benzylic alcohols to the corresponding aldehyde,[234] and dioxirane reagents are sufficiently mild that an α,β-epoxy alcohol was oxidized to the corresponding ketone, without disturbing the epoxide, using methyl trifluoromethyl dioxirane.[235] Hydrogen peroxide with urea oxidizes aryl aldehydes in formic acid.[236] Potassium monoperoxysulfate in the presence of a

chiral ketone oxidizes 1,2-diols to α-hydroxy ketones enantioselectively.[237] Potassium monoperoxysulfate also oxidizes secondary alcohols in the presence of O_2.[238] air in the presence of a zeolite oxidizes benzylic alcohols. [239] The reagent $Br^+(collidine)_2PF_6$ oxidizes benzylic alcohols to the corresponding aldehyde.[240] Sodium hypochlorite in acetic acid is useful for oxidizing larger amounts of secondary alcohols.[241] Calcium hypochlorite on moist alumina with microwave irradiation has been used to oxidize benzylic alcohols.[242] Chlorosulfimines, Ar(Cl)S=N—*t*-Bu, oxidize primary alcohols to aldehydes.[243] This latter reagent is generated from ArS—NH*t*-Bu and NCS.[244] Benzylic alcohols are converted to aldehydes with DBU (p. $$$) and Ar_3BCl_2.[245] Microwave irradiation of benzylic alcohols with $Co(CO_3)_2$ on silica gel generates the aryl aldehyde.[246]

Primary and secondary alcohols can also be oxidized, indirectly, through their esters (see **19-21**). In some cases, isolation of the ester is not required and the alcohol can then be oxidized to the aldehyde or ketone in one step.

The mechanism of oxidation with acid dichromate has been intensely studied.[247] The currently accepted mechanism is essentially that proposed by Westheimer.[248] The first two steps constitute an example of category 4 (p. 1706).

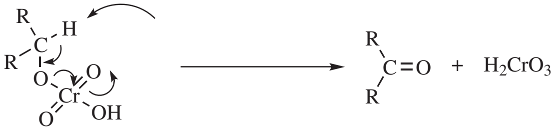
The base in the second step may be water, although it is also possible[249] that in some cases no external base is involved and that the proton is transferred directly to one of the CrO_3H oxygens in which case the Cr(IV) species



produced would be H_2CrO_3. Part of the evidence for this mechanism was the isotope effect of ~ 6 found on use of MeCDOHMe, showing that the a hydrogen is removed in the rate-determining step.[250] Note that, as in **19-23** the substrate is oxidized by three different oxidation states of chromium.[251]

With other oxidizing agents, mechanisms are less clear.[252] It seems certain that some oxidizing agents operate by a hydride-shift mechanism,[253] for example,

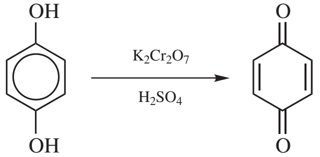
19-4 Oxidation of Phenols and Aromatic Amines to Quinones

1/*O*,6/*O*-Dihydro-elimination



Ortho and para diols are easily oxidized to ortho- and para-quinones, respectively.[258] Either or both OH groups can be replaced by NH_2 groups to give the same products, although for the preparation of ortho-quinones only OH groups are normally satisfactory. The reaction has been successfully carried out with other groups para to OH or NH_2; halogen, OR, Me, *t*-Bu, and even H, although with the last yields are poor. Many oxidizing agents have been used: acid dichromate,[259] silver oxide, silver carbonate, lead tetraacetate, HIO_4, NBS—H_2O—H_2SO_4,[260] MnO_2 on Bentonite with microwave irradiation,[261] dimethyl dioxirane,[262] and atmospheric oxygen,[263] to name a few. Substituted phenols, such as 4-($CH_2CH_2CH_2COOH$) phenol, are oxidized with a polymer-bound hypervalent iodine reagent to give a quinone with a spirocyclic lactone unit at C-4.[264] Oxidation

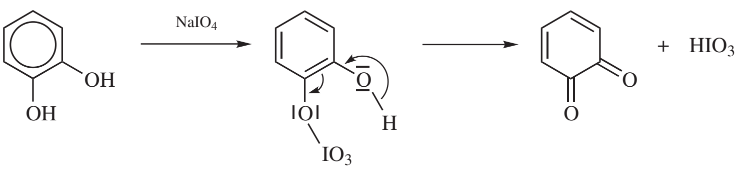
has been done photochemically with O_2 and tetraphenylporphine.[265] A particularly effective reagent for rings with only one OH or NH_2 group is $(KSO_3)_2N$—O• (dipotassium nitrosodisulfonate; *Fremy's salt*), which is a stable free radical.[266] Phenols, even some whose para positions are unoccupied, can be oxidized to ortho-quinones with diphenylseleninic anhydride.[267] Quinoid coupling products are obtained from substituted phenol treated with O_2, a dicopper complex, and mushroom tyrosinase.[268]

Less is known about the mechanism than is the case for **19-3**, but, as in that case, it seems to vary with the oxidizing agent. For oxidation of catechol with $NaIO_4$, it was found that the reaction conducted in $H_2{}^{18}O$ gave unlabeled quinone,[269] so the following mechanism[270] was proposed:



When catechol was oxidized with MnO_4^- under aprotic conditions, a semiquinone radical ion intermediate was involved.[271] For autoxidations[272] (i.e., with atmospheric oxygen) a free-radical mechanism is known to operate.[273]

19-5 Dehydrogenation of Amines

1/1/*N*,2/2/*C*-Tetrahydro-bielimination

$$RCH_2NH_2 \longrightarrow RCN$$

Primary amines at a primary carbon can be dehydrogenated to nitriles. The reaction has been carried out with a variety of reagents, among others, lead tetraacetate,[274] NaOCl,[275]

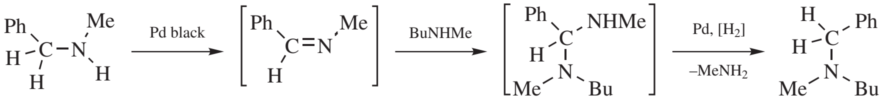
$K_2S_2O_8/NiSO_4$,[276] $Me_3N/O/OsO_4$,[277] $Ru/Al_2O_3/O_2$,[278] and $CuCl/O_2$/pyridine.[279] Several methods have been reported for the dehydrogenation of secondary amines to imines.[280] Among them[281] are treatment with (*1*) iodosylbenzene (PhIO) alone or in the presence of a ruthenium complex,[282] (*2*) DMSO and oxalyl chloride,[283] and (*3*) *t*-BuOOH and a rhenium catalyst.[284] *N*-Tosyl aziridines are converted to *N*-tosyl imines when heated with a palladium catalyst.[285] An interesting variation treats pyrrolidine with iodobenzene and a rhodium catalyst to give 2-phenylpyrroline.[286]

A reaction that involves dehydrogenation to an imine that then reacts further is the reaction of primary or secondary amines[287] with palladium black.[288] The imine initially formed by the dehydrogenation reacts with another molecule of the same or a different amine to give an aminal, which loses NH_3 or RNH_2 to give a secondary or tertiary amine. An example is the reaction between *N*-methylbenzylamine and butylmethylamine, which produces 95% *N*-methyl-*N*-butylbenzylamine.



19-6 Oxidation of Hydrazines, Hydrazones, and Hydroxylamines

1/*N*,2/*N*-Dihydro-elimination

$$\text{Ar—NH—NH—Ar} \xrightarrow{\text{NaOBr}} \text{Ar—N=N—Ar}$$

N,N'-Diarylhydrazines (hydrazo compounds) are oxidized to azo compounds by several oxidizing agents, including NaOBr, HgO,[289] $K_3Fe(CN)_6$ under phase-transfer

conditions[290] or with galvinoxyl,[291] $FeCl_3$,[292] MnO_2 (this reagent yields cis-azobenzenes),[293] $CuCl_2$, and air and NaOH.[294] The reaction is also applicable to *N,N′*-dialkyl- and *N,N′*-diacylhydrazines. Hydrazines (both alkyl and aryl) substituted on only one side also give azo compounds,[295] but these are unstable and decompose to nitrogen and the hydrocarbon:

$$\text{Ar—NH—NH}_2 \longrightarrow [\text{Ar—N=NH}] \longrightarrow \text{ArH} + \text{N}_2$$

Aniline derivatives are converted to azo compounds by heating with cetyltrimethylammonium dichromate in chloroform.[296] When hydrazones are oxidized with HgO, Ag_2O, MnO_2, lead tetraacetate, or certain other oxidizing agents, diazo compounds are obtained:[297]

$$\text{R}_2\text{C=N—NH}_2 \xrightarrow{\text{HgO}} \text{R}_2\text{C=}\overset{\oplus}{\text{N}}\text{=}\overset{\ominus}{\text{N}}$$

Hydrazones of the form $ArCH{=}NNH_2$ react with HgO in solvents, such as diglyme or ethanol, to give nitriles ArCN.[298] It is possible to oxidize dimethylhydrazones ($R{-}C{=}N{-}NMe_2$) to the corresponding nitrile ($R{-}C{\equiv}N$) with $MeReO_3$/H_2O_2[299] magnesium monoperoxyphthalate (MMPP),[300] or with dimethyl dioxirane.[301] Oxone® on wet alumina also converts hydrazones to nitriles with microwave irradiation.[302]

In a related reaction, primary aromatic amines have been oxidized to azo compounds by a variety of oxidizing agents, among them MnO_2, lead tetraacetate, O_2 and a base, barium permanganate,[303] and sodium perborate in acetic acid. *tert*-Butyl hydroperoxide has been used to oxidize certain primary amines to azoxy compounds.[304] Aromatic hydroxylamines (Ar—NH—OH) are easily oxidized to nitroso compounds (Ar—N=O), most commonly by acid dichromate.[305] Oximes of

aromatic aldehydes are converted to aryl nitriles with $InCl_3$[306] (ketoximes give a Beckmann rearrangement, **18-17**).

Nitrones, $C{=}N^+(R){=}O^-$, are generated by the oxidation of *N*-hydroxyl secondary amines with 5% aq. NaOCl.[307] Secondary amines, such as dibenzylamine, can be converted to the corresponding nitrone by heating with cumyl hydroperoxide in the presence of a titanium catalyst.[308] Imines are oxidized to amides with mcpba and BF_3•OEt_2.[309]

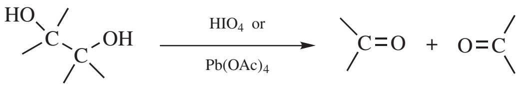
B. Oxidations Involving Cleavage of Carbon–Carbon Bonds[310]

19-7 Oxidative Cleavage of Glycols and Related Compounds

2/*O*-De-hydrogen-uncoupling



1,2-Glycols are easily cleaved under mild conditions and in good yield with periodic acid or lead tetraacetate.[311] The products are 2 equivalents of aldehyde, or 2 equivalents of ketone, or 1 equivalent of each, depending on the groups attached to the two carbons. The yields are so good that alkenes are often converted to glycols (**15-48**), and then cleaved with HIO_4 or $Pb(OAc)_4$ rather than being cleaved directly with ozone (**19-9**) or dichromate or permanganate (**19-10**). The diol can be generated and cleaved *in situ* from an alkene to give the carbonyl compounds.[312]

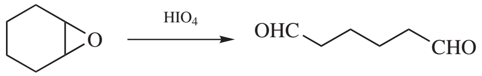
A number of other oxidizing agents also give the same products, among them[313] activated MnO_2,[314] O_2 and a ruthenium catalyst,[315] PPh_3–DEAD,[316] and pyridinium chlorochromate.[317] Permanganate, dichromate, and several other oxidizing agents[318] also cleave glycols, giving carboxylic acids rather than aldehydes, but these reagents are seldom used synthetically. Electrochemical oxidation is an efficient method, and is useful not only for diols, but also for their mono- and dimethoxy derivatives.[319]

The two reagents (periodic acid and lead tetraacetate) are complementary, since periodic acid is best used in water and lead tetraacetate in organic solvents. Chiral lead carboxylates have been prepared for the oxidative cleavage of 1,2-diols.[320] When three or more OH groups are located on adjacent carbons, the middle one (or ones) is converted to formic acid.

Other compounds that contain oxygens or nitrogens on adjacent carbons undergo similar cleavage:

β-Amino alcohols | 1,2-Diamines | α-Hydroxy aldehydes and ketones | α-Diketones a-keto aldehydes Glyoxal

Cyclic 1,2-diamines are cleaved to diketones with dimethyl dioxirane.[321] α-Diketones and α-hydroxy ketones are also cleaved by alkaline H_2O_2.[322] The HIO_4 has been used to cleave epoxides to aldehydes,[323] for example,



α-Hydroxy acids and α-keto acids are not cleaved by HIO_4, but are cleaved by $NaIO_4$ in methanol in the presence of a crown ether,[324] $Pb(OAc)_4$, alkaline H_2O_2,

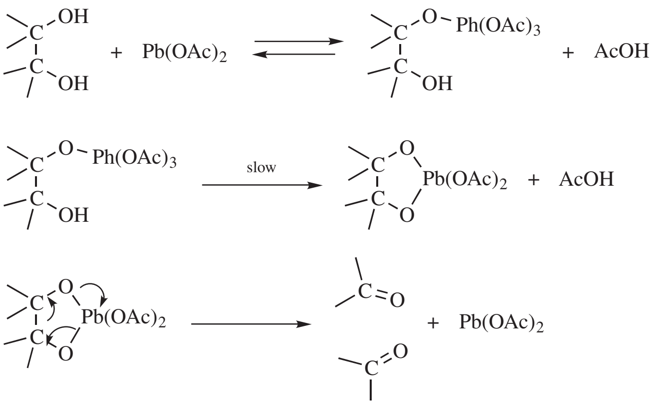
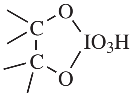
and other reagents. These are oxidative decarboxylations. α-Hydroxy acids give aldehydes or ketones, and α-keto acids give carboxylic acids. Also see, **19-12** and **19-13**.

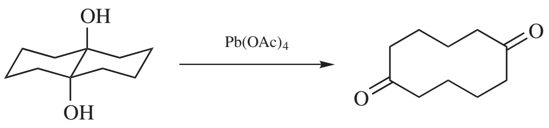
The mechanism of glycol oxidation with $Pb(OAc)_4$ was proposed by Criegee:[325]



This mechanism is supported by these facts: (*1*) the kinetics are second order (first order in each reactant); (*2*) added acetic acid retards the reaction (drives the equilibrium to the left); and (*3*) cis-glycols react much more rapidly than trans-glycols.[326] For periodic acid, the mechanism is similar, with the intermediate[327]



However, the cyclic-intermediate mechanism cannot account for all glycol oxidations, since some glycols that cannot form such an ester (e.g., **15**) are nevertheless cleaved by lead tetraacetate



15

[325]Criegee, R.; Kraft, L.; Rank, B. *Liebigs Ann. Chem.* ***1933***, *507*, 159. For reviews, see Waters, W.A. *Mechanisms of Oxidation of Organic Compounds*, Wiley, NY, ***1964***, pp. 72–81; Stewart, R. *Oxidation Mechanisms*, W.A. Benjamin, NY, ***1964***, pp. 97–106.

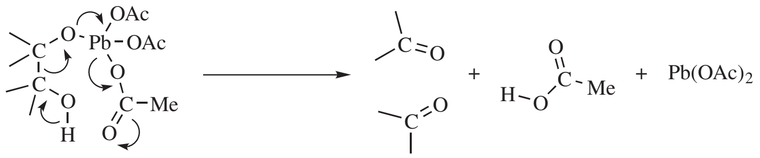
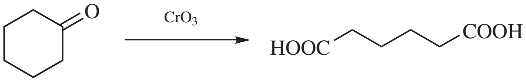
(though other glycols that cannot form cyclic esters are *not* cleaved, by either reagent[328]). To account for cases like **15**, a cyclic transition state has been proposed:[326]



OS **IV**, 124; **VII**, 185; **VIII**, 396.

19-8 Oxidative Cleavage of Ketones, Aldehydes, and Alcohols

Cycloalkanone oxidative ring opening



Oxidative cleavage of open-chain ketones or alcohols[329] is seldom a useful preparative procedure, not because these compounds do not undergo oxidation (they do, except for diaryl ketones), but because the result is generally a hopeless mixture. Aryl methyl ketones, such as acetophenone, however, are readily oxidized to aryl carboxylic acids with Re_2O_7 and 70% aqueous *tert*-butyl hydroperoxide.[330] Oxygen with a mixture of manganese and cobalt catalysts give similar oxidative cleavage,[331] and do hypervalent iodine compounds.[332] 1,3-Diketones, such as 1,3-diphenyl-1,3-propanedione, are oxidatively cleaved with aqueous Oxone® to give benzoic acid.[333] Noted that in the presence of benzaldehyde, aliphatic ketones are cleaved to give aliphatic carboxylic acids by treatment with BF_3(g) in refluxing hexane.[334] Aldehydes, such as $PhCH_2CHO$, are cleaved to benzaldehyde with phosphonium dichromate in refluxing acetonitrile.[335]

Despite problems with acyclic ketones, the reaction is quite useful for cyclic ketones and the corresponding secondary alcohols, the dicarboxylic acid being prepared in good yield. The formation of adipic acid from cyclohexanone (shown above) is an important industrial procedure. Acid dichromate and permanganate are the most common oxidizing agents, although autoxidation (oxidation with

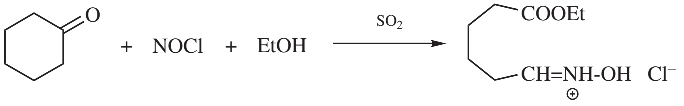
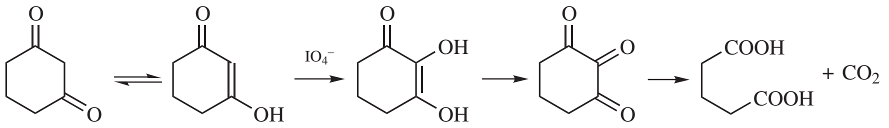
atmospheric oxygen) in alkaline solution[336] and potassium superoxide under phase-transfer conditions[337] have also been used. Other reagents include LiOCl/Chlorox[338] and $MeOCO_2Me$ at 195°C.[339] Silyl-ketones have been cleaved to esters using electrolysis in alcohol solvents.[340] Cyclic 1,3-diketones are converted to α,ω-diesters with an excess of $KHSO_5$ in methanol.[341] Cyclic α-chloro ketones are cleaved to give an α,ω-functionalized compound (acetal-ester) when treated with cerium (IV) sulfate tetrahydrate and O_2.[342]

Cyclic ketones can also be cleaved by treatment with NOCl and an alcohol in liquid SO_2 to give an ω-oximinocarboxylic ester, for example,[343]



Cyclic 1,3-diketones, which exist mainly in the mono-enolic form, can be cleaved with sodium periodate with loss of one carbon, for example,[344]



The species actually undergoing the cleavage is the triketone, so this is an example of **19-7**.

When compounds containing double bonds are treated with ozone, usually at low temperatures, they are converted to compounds called *ozonides* (**16**) that can be isolated but, because some of them are explosive, are more often decomposed with zinc and acetic acid, or catalytic hydrogenation to give 2 equivalents of aldehyde, or 2 equivalents of ketone, or 1 equivalent of each, depending on the groups attached to the alkene.[345] The decomposition of **16** has also been carried out with triethylamine[346] and with reducing agents, among them trimethyl phosphite,[347] thiourea,[348] and dimethyl sulfide.[349] However, ozonides can also be *oxidized* with oxygen, peroxyacids, or H_2O_2 to give ketones and/or carboxylic acids or *reduced* with $LiAlH_4$, $NaBH_4$, BH_3, or catalytic hydrogenation with excess H_2 to give 2 equivalents alcohol.[350] Ozonides can also be treated with ammonia, hydrogen, and a catalyst to give the corresponding amines,[351] or with an alcohol and anhydrous HCl to give the corresponding carboxylic esters.[352] Ozonolysis is therefore an important synthetic reaction.

A wide variety of alkenes undergo ozonolysis, including cyclic ones, where cleavage gives rise to one bifunctional product. Alkenes in which the double bond is connected to electron-donating groups react many times faster than those in which it is connected to electron-withdrawing groups.[353] The reaction has often been carried out on compounds containing more than one double bond; generally all the bonds are cleaved. In some cases, especially when bulky groups are present, conversion of the substrate to an epoxide (**15-50**) becomes an important side reaction and can be the main reaction.[354] Rearrangement is possible in some cases.[355] Ozonolysis of triple bonds[356] is less common and the reaction proceeds less easily,

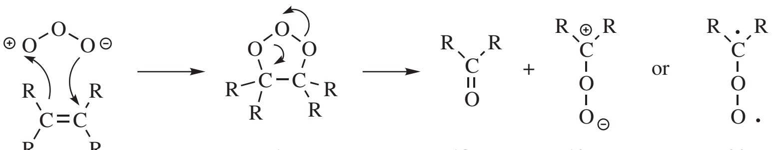
since ozone is an electrophilic agent[357] and prefers double to triple bonds (p. 1017). Compounds that contain triple bonds generally give carboxylic acids, although sometimes ozone oxidizes them to α-diketones (**19-26**). Aromatic compounds are also attacked less readily than alkenes, but have often been cleaved. Aromatic compounds behave as if the double bonds in the Kekulé structures were really there. Thus benzene gives three equivalents of glyoxal (HCOCHO), and *o*-xylene gives a glyoxal/MeCOCHO/MeCOCOMe ratio of 3:2:1, which shows that in this case cleavage is statistical. With polycyclic aromatic compounds the site of attack depends on the structure of the molecule and on the solvent.[358]



17 **18** **19** **20**

Although a large amount of work has been done on the mechanism of ozonization (formation of **16**), not all the details are known. The basic mechanism was formulated by Criegee.[359] The first step of the Criegee mechanism[360] is a 1,3-dipolar addition (**15-58**) of ozone to the substrate to give the "initial" or "primary" ozonide, the structure of which has been shown to be the 1,2,3-trioxolane, **17**, by microwave and other spectral methods.[361] A primary ozonide has been trapped.[362] However, **17** is highly unstable and cleaves to an aldehyde or ketone (**18**) and an intermediate,[363] which Criegee showed as a zwitterion (**19**), but which may be a diradical (**20**). This compound is usually referred to as a carbonyl oxide.[364] The carbonyl oxide (which we will represent as **19**) can then undergo various reactions, three of which lead to normal products. One is a recombination with **18**, the second

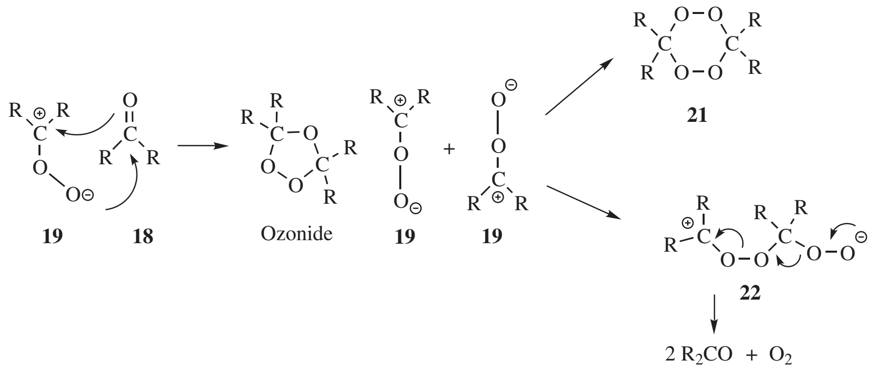
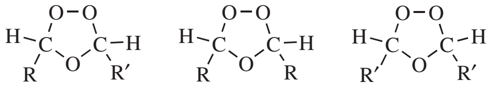
a dimerization to the bis(peroxide) **21**, and the third a kind of dimerization to **22**.[365] If the first path is taken (this is normally



possible only if **15** is an aldehyde; most ketones do not do this[366]) the product is an ozonide (a 1,2,4-trioxolane),[367] and hydrolysis of the ozonide gives the normal products. If **21** is formed, hydrolysis of it gives one of the products, and, of course, **18**, which then does not undergo further reaction, is the other. Intermediate **22**, if formed, can decompose directly, as shown, to give the normal products and oxygen. In protic solvents, **19** is converted to a hydroperoxide, and these have been isolated, for example,

from $Me_2C{=}CMe_2$ in methanol. Further evidence for the mechanism is that **21** can be isolated in some cases, for example, from $Me_2C{=}CMe_2$. But perhaps the most impressive evidence comes from the detection of cross-products. In the Criegee mechanism, the two parts of the original alkene break apart and then recombine to form the ozonide. In the case of an unsymmetrical alkene, RCH=CHR′, there should be three ozonides:

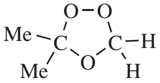


[365]Fliszár, S.; Chyliń ska, J.B. *Can. J. Chem.* ***1967***, *45*, 29; ***1968***, *46*, 783.

[366]It follows that tetrasubstituted alkenes do not normally give ozonides. However, they do give the normal cleavage products (ketones) by the other pathways. For the preparation of ozonides from tetrasubstituted alkenes by ozonolysis on polyethylene, see Griesbaum, K.; Volpp, W.; Greinert, R.; Greunig, H.; Schmid, J.; Henke, H. *J. Org. Chem.* ***1989***, *54*, 383.

[367]Kamata, M.; Komatsu, K.i.; Akaba, R. *Tetrahedron Lett.* ***2001***, *42*, 9203. For a report of an isolable ozonide, see dos Santos, C.; de Rosso, C.R.S.; Imamura, P.M. *Synth. Commun.* ***1999***, *29*, 1903.

since there are two different aldehydes **18** and two different species **19**, and these can recombine in the three ways shown. Actually *six* ozonides, corresponding to the cis and trans forms of these three, were isolated and characterized for methyl oleate.[368] Similar results have been reported for smaller alkenes, for example, 2-pentene, 4-nonene, and even 2-methyl-2-pentene.[369] The last-mentioned case is especially interesting, since it is quite plausible that this compound would cleave in only one way, so that only one ozonide (in cis and trans versions) would be found; but this is not so, and three were found for this case too. However, terminal alkenes give little or no cross-ozonide formation.[370] In general, the less alkylated end of the alkene tends to go to **18** and the other to **19**. Still other evidence[371] for the Criegee mechanism is (*1*) When $Me_2C{=}CMe_2$ was ozonized in the presence of



23

HCHO, the ozonide **23** could be isolated;[372] (*2*) **19** prepared in an entirely different manner (photooxidation of diazo compounds), reacted with aldehydes to give ozonides;[373] and (*3*) cis- and trans-alkenes generally give the same ozonide, which would be expected if they cleave first.[374] However, this was not true for $Me_3CCH{=}CHCMe_3$, where the cis-alkene gave the cis-ozonide (chiefly), and the trans gave the trans.[375] The latter result is not compatible with the Criegee mechanism. Also incompatible with the Criegee mechanism was the finding that the cis/trans ratios of symmetrical (cross) ozonides obtained from *cis*- and *trans*-4-methyl-2-pentene were not the same.[376]

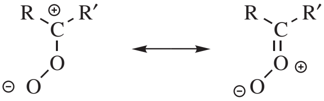
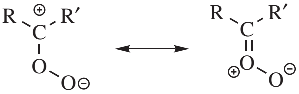
				50-50 cis–trans	48-52 cis–trans	38-62 cis–trans
	66-34 cis–trans	49-51 cis–trans	49-51 cis–trans

If the Criegee mechanism operated as shown above, the cis/trans ratio for each of the two cross-ozonides would have to be identical for the cis- and trans-alkenes, since in this mechanism they are completely cleaved.

The above stereochemical results have been explained[377] on the basis of the Criegee mechanism with the following refinements: (*1*) The formation of **17** is stereospecific, as expected from a 1,3-dipolar cycloaddition. (*2*) Once they are formed, **19** and **18** remain attracted to each other, much like an ion pair. (*3*) Intermediate **19** exists in syn and anti forms, which are produced in different amounts and can hold their shapes, at least for a time. This is



syn-**16**



anti-**16**

plausible if we remember that a C=O canonical form contributes to the structure of **19**. (*4*) The combination of **19** and **18** is also a 1,3-dipolar cycloaddition, so configuration is retained in this step too.[378]

Evidence that the basic Criegee mechanism operates even in these cases comes from ^{18}O labeling experiments, making use of the fact, mentioned above, that mixed ozonides (e.g., **23**) can be isolated when an external aldehyde is added. Both the normal and modified Criegee mechanisms predict that if ^{18}O-labeled aldehyde is added to the ozonolysis mixture, the label will appear in the ether oxygen (see the reaction between **19** and **18**), and this is what is found.[379] There is evidence that the *anti*-**19** couples much more readily than the *syn*-**19**. [380]

[377]Bauld, N.L.; Thompson, J.A.; Hudson, C.E.; Bailey, P.S. *J. Am. Chem. Soc.* ***1968***, *90*, 1822; Bailey, P.S.; Ferrell, T.M. *J. Am. Chem. Soc.* ***1978***, *100*, 899; Keul, H.; Kuczkowski, R.L. *J. Am. Chem. Soc.* ***1985***, *50*, 3371.

[378]For isotope-effect evidence that this step is concerted in some cases, see Choe, J.; Painter, M.K.; Kuczkowski, R.L. *J. Am. Chem. Soc.* ***1984***, *106*, 2891. However, there is evidence that it may not always be concerted: See, for example, Murray, R.W.; Su, J. *J. Org. Chem.* ***1983***, *48*, 817.

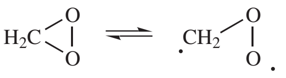
[380]Mile, B.; Morris, G.M. *J. Chem. Soc. Chem. Commun.* ***1978***, 263.

The ozonolysis of ethylene[381] in the liquid phase (without a solvent) was shown to take place by the Criegee mechanism.[382] This reaction has been used to study the structure of the intermediate **19** or **20**. The compound dioxirane (**24**) was identified in the reaction mixture[383] at low temperatures and is probably in equilibrium with the biradical **20** (R = H). Dioxirane has been produced in solution, but it oxidatively cleaves dialkyl ethers (e.g., Et—O—Et) via a chain radical process, [384] so the choice of solvent is important.



24 **20** (R = H)

Ozonolysis in the gas phase is not generally carried out in the laboratory. However, the reaction is important because it takes place in the atmosphere and contributes to air pollution.[385] There is much evidence that the Criegee mechanism operates in the gas phase too, although the products are more complex because of other reactions that also take place.[386]

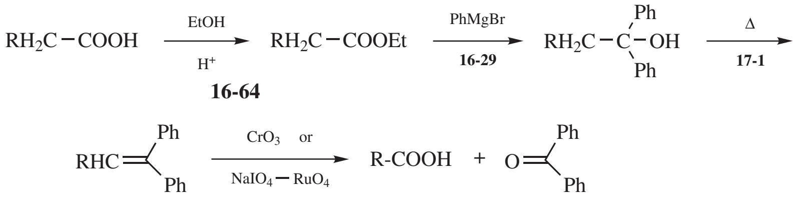
products are generally 2 equivalents of ketone, 2 equivalents of carboxylic acid, or 1 equivalent of each, depending on what groups are attached to the alkene. With ordinary solutions of permanganate or dichromate yields are generally low, and the reaction is seldom a useful synthetic method; but high yields can be obtained by oxidizing with $KMnO_4$ dissolved in benzene containing the crown ether dicyclohexano-18-crown-6 (see p. 120).[388] The crown ether coordinates with K^+, permitting the $KMnO_4$ to dissolve in benzene. A mixture of aq. $KMnO_4$ and $NaIO_4$ on sand is also effective.[389] Another reagent frequently used for synthetic purposes is the *Lemieux–von Rudloff reagent*: HIO_4 containing a trace of MnO_4^-.[390] The MnO_4^- is the actual oxidizing agent, being reduced to the manganate stage, and the purpose of the HIO_4 is to reoxidize the manganate back to MnO_4^-. Another reagent that behaves similarly is $NaIO_4$–ruthenium tetroxide.[391] Cyclic alkenes are cleaved to α,ω-diketones, keto-acids or dicarboxylic acids. Cyclic alkenes are cleaved to dialdehydes with $KMnO_4$•$CuSO_4$ in dichloromethane.[392] Hydrogen peroxide on supported heteropolyacid cleaves cyclic alkenes.[393] A combination of $RuCl_3/HIO_5$ oxidatively cleaves cyclic alkenes to dicarboxylic acids.[394]

The *Barbier–Wieland procedure* for decreasing the length of a chain by one carbon involves oxidative cleavage by acid dichromate ($NaIO_4$–ruthenium tetroxide has also been used), but this is cleavage of a 1,1-diphenyl alkene, which generally gives good yields:



Addition of a catalytic amount of OsO_4 to Jones reagent (**19-3**) leads to good yields of the carboxylic acid from simple alkenes.[395] A combination of Oxone® and OsO_4 in DMF cleaves alkenes to carboxylic acids.[396] With certain reagents, the oxidation of double bonds can be stopped at the aldehyde stage, and in these cases the products are the same as in the ozonolysis procedure. Among these reagents are

tert-butyl iodoxybenzene,[397] $KMnO_4$ in THF–H_2O,[398] and $NaIO_4$–OsO_4.[399] Electrolysis with $LiClO_4$ in aqueous acetonitrile also cleaves alkenes to give the aldehyde.[400] Enol ethers, RC(OR′)=CH_2, have been cleaved to carboxylic esters, RC(OR′)=O, by atmospheric oxygen.[401]

Cleavage of alkynes is generally rather difficult, but treatment of internal alkynes with an excess of Oxone® with a ruthenium catalyst leads to aliphatic carboxylic acids.[402]

The mechanism of oxidation probably involves in most cases the initial formation of a glycol (**15-29**) or cyclic ester,[403] and then further oxidation as in **19-7**.[404] In line with the electrophilic attack on the alkene, triple bonds are more resistant to oxidation than double bonds. Terminal triple-bond compounds can be cleaved to carboxylic acids ($RC{\equiv}CH \longrightarrow RCOOH$) with thallium(III) nitrate[405] or with [bis-(trifluoroacetoxy)iodo]pentafluorobenzene [i.e., $C_6F_5I(OCOCF_3)_2$],[406] among other reagents.

Aromatic rings can be cleaved with strong enough oxidizing agents. An important laboratory reagent for this purpose is ruthenium tetroxide along with a co-oxidant, such as $NaIO_4$ or NaOCl (household bleach can be used).[407] Examples[408] are the oxidation of naphthalene to phthalic acid[409] and, even more remarkably, of cyclohexylbenzene to cyclohexanecarboxylic acid[410] (note the contrast with **19-11**). The latter conversion was also accomplished with ozone.[411] Another reagent that oxidizes aromatic rings is air catalyzed by V_2O_5. The oxidations of naphthalene to phthalic anhydride and of benzene to maleic anhydride by this reagent are

19-11 Oxidation of Aromatic Side Chains

Oxo,hydroxy-de-dihydro,methyl-tersubstitution

$$\mathrm{ArR} \xrightarrow{\mathrm{KMnO_4}} \mathrm{ArCOOH}$$

Alkyl chains on aromatic rings can be oxidized to COOH groups by many oxidizing agents, including permanganate, nitric acid, and acid dichromate.[417] The method is most often applied to the methyl group, although longer side chains can also be cleaved. However, tertiary alkyl groups are resistant to oxidation, and when they *are* oxidized, ring cleavage usually occurs too.[418] It is usually difficult to oxidize an R group on a fused aromatic system without cleaving the ring or oxidizing it to a quinone (**19-19**). However, this has been done (e.g., 2-methylnaphthalene was converted to 2-naphthoic acid) with aqueous $Na_2Cr_2O_7$.[419] Aryl methyl groups are oxidized to aryl COOH with NaOCl in acetonitrile,[420] or with NBS in aq. NaOH under photochemical conditions.[421] Functional groups can be present anywhere on the side chain and, if in the α position, greatly increase the ease of oxidation. An exception is an a phenyl group. In such cases, the reaction stops at the diaryl ketone stage. Molecules containing aryl groups on different carbons cleave so that each

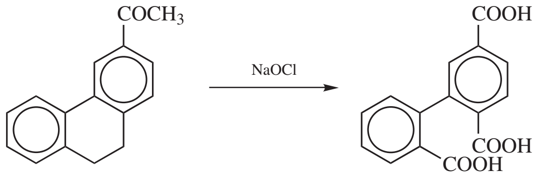
ring gets one carbon atom, as in the clevvage of the 9,10-bond of dihydrophenanthrenes **25** to **26**.



25 **26**

It is possible to oxidize only one alkyl group of a ring that contains more than one. The order of reactivity[422] toward most reagents is $CH_2Ar > CHR_2 > CH_2R > CH_3$.[423] Groups on the ring susceptible to oxidation (OH, NHR, NH_2, etc.) must be protected. The oxidation can be performed with oxygen, in which case it is autoxidation, and the mechanism is like that in **14-7**, with a hydroperoxide intermediate. With this procedure it is possible to isolate ketones from $ArCH_2R$, and this is often done.[424]

The mechanism has been studied for the closely related reaction: $Ar_2CH_2 + CrO_3 \rightarrow Ar_2C{=}O$.[425] A deuterium isotope effect of 6.4 was found, indicating that the rate-determining step is either $Ar_2CH_2 \rightarrow Ar_2CH\bullet$ or $Ar_2CH_2 \rightarrow Ar_2CH^+$. Either way this explains why tertiary groups are not converted to COOH and why the reactivity order is $CHR_2 > CH_2R > CH_3$, as mentioned above. Both free radicals and carbocations exhibit this order of stability (Chapter 5). The two possibilities are examples of categories 2 and 3 (p. 1706). Just how the radical or the cation goes on to the product is not known.

When the alkyl group is one oxidizable to COOH (**19-11**), cupric salts are oxidizing agents, and the OH group is found in a position ortho to that occupied by the alkyl group.[426] This reaction is used industrially to convert toluene to phenol.

In another kind of reaction, an aromatic aldehyde ArCHO or ketone ArCOR′ is converted to a phenol ArOH on treatment with alkaline H_2O_2,[427] but there must be an OH or NH_2 group in the ortho or para position. This is called the *Dakin reaction*.[428] The mechanism may be similar to that of the Baeyer–Villiger reaction (**18-19**):[429]

[422]Oxidation with Co(III) is an exception. The methyl group is oxidized in preference to the other alkyl groups: Onopchenko, A.; Schulz, J.G.D.; Seekircher, R. *J. Org. Chem.* ***1972***, *37*, 1414.

[423]For example, see Foster, G.; Hickinbottom, W.J. *J. Chem. Soc.* ***1960***, 680; Ferguson, L.N.; Wims, A.I. *J. Org. Chem.* ***1960***, *25*, 668.

27

The intermediate **27** has been isolated.[430] The reaction has been performed on aromatic aldehydes with an alkoxy group in the ring, and no OH or NH_2. In this case, acidic H_2O_2 was used.[431] The Dakin reaction has been done in ionic liquids.[432]

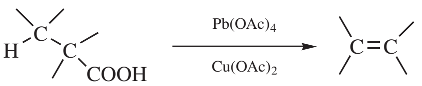
19-12 Oxidative Decarboxylation
Acetoxy-de-carboxy-substitution

$$\text{RCOOH} \xrightarrow{\text{Pb(OAc)}_4} \text{ROAc}$$

Hydro-carboxyl-elimination



Carboxylic acids can be decarboxylated[433] with lead tetraacetate to give a variety of products, among them the ester ROAc (formed by replacement of COOH by an acetoxy group), the alkane RH (see **12-40**), and, if α,β hydrogen is present, the alkene formed by elimination of H and COOH, as well as numerous other products arising from rearrangements, internal cyclizations,[434] and reactions with solvent molecules. When R is tertiary, the chief product is usually the alkene, which is often obtained in good yield. High yields of alkenes can also be obtained when R is primary or secondary, in this case by the use of $Cu(OAc)_2$ along with the $Pb(OAc)_4$.[435] In the absence of $Cu(OAc)_2$, primary acids give mostly alkanes (though yields are

generally low) and secondary acids may give carboxylic esters or alkenes. Carboxylic esters have been obtained in good yields from some secondary acids, from β,γ-unsaturated acids, and from acids in which R is a benzylic group. Other oxidizing agents,[436] including Co(III), Ag(II), Mn(III), and Ce(IV), have also been used to effect oxidative decarboxylation.[437]

The mechanism with lead tetraacetate is generally accepted to be of the free-radical type.[438] First, there is an interchange of ester groups:

$$Pb(OAc)_4 + RCOOH \longrightarrow \underset{\textbf{28}}{Rb(OAc)_3OCOR} \quad \text{or} \quad \underset{\textbf{29}}{Pb(OAc)_2(OCOR)_2}$$

There follows a free-radical chain mechanism (shown for **28** although **29** and other lead esters can behave similarly)

$$\underset{\textbf{23}}{Pb(OAc)_3OCOR} \longrightarrow \bullet Pb(OAc)_3 + R\bullet + CO_2$$

Initiation

$$R\bullet + Pb(OAc)_3OCOR \longrightarrow R^+ + \bullet Pb(OAc)_2OCOR + OAc^-$$

$$\bullet Pb(OAc)_2OCOR \longrightarrow Pb(OAc)_2 + R\bullet + CO_2$$

Propagation

Products can then be formed either from R• or R^+. Primary R• abstract H from solvent molecules to give RH. R^+ can lose H^+ to give an alkene, react with HOAc to give the carboxylic ester, react with solvent molecules or with another functional group in the same molecule, or rearrange, thus accounting for the large number of possible products. The R• group can also dimerize to give RR. The effect of Cu^{2+} ions[439] is to oxidize the radicals to alkenes, thus producing good yields of alkenes from primary and secondary substrates. The Cu^{2+} ion has no effect on tertiary radicals, because these are efficiently oxidized to alkenes by lead tetraacetate.

$$H{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}\bullet + Cu^{2+} \longrightarrow >C{=}C< + H^+ + Cu^+$$

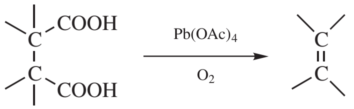
In another type of oxidative decarboxylation, arylacetic acids can be oxidized to aldehydes with one less carbon ($ArCH_2COOH \rightarrow ArCHO$) by tetrabutylammonium periodate.[440] Simple aliphatic carboxylic acids were converted to nitriles with one less carbon ($RCH_2COOH \rightarrow RC{\equiv}N$) by treatment with trifluoroacetic anhydride and $NaNO_2$ in F_3CCOOH.[441]

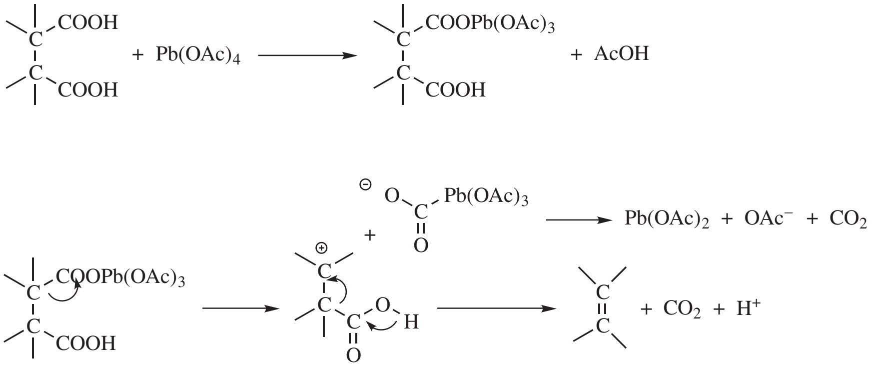
See also, **14-37**.

19-13 Bisdecarboxylation

Dicarboxy-elimination



Compounds containing carboxyl groups on adjacent carbons (succinic acid derivatives) can be bisdecarboxylated with lead tetraacetate in the presence of O_2.[433] The reaction is of wide scope. The elimination is stereoselective, but not stereospecific (both *meso*- and *dl*-2,3-diphenylsuccinic acid gave *trans*-stilbene);[442] a concerted mechanism is thus unlikely. The following mechanism is not inconsistent with the data:



though a free-radical mechanism seems to hold in some cases. Bis(decarboxylation) of succinic acid derivatives to give alkenes[443] has also been carried out by other methods, including treatment of the corresponding anhydrides with nickel, iron,

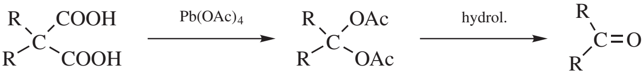
or rhodium complexes,[444] by decomposition of the corresponding bis(peroxyesters),[445] and electrolytically.[446]

Compounds containing geminal carboxyl groups (disubstituted malonic acid derivatives) can also be bisdecarboxylated with lead tetraacetate,[447] *gem*-diacetates (acylals) being produced, which are easily hydrolyzable to ketones:[448]



A related reaction involves α-substituted aryl nitriles having a sufficiently acidic α hydrogen, which can be converted to ketones by oxidation with air under phase transfer conditions.[449] The nitrile is added to NaOH in benzene or DMSO containing a catalytic amount of triethylbenzylammonium chloride (TEBA).[450] This reaction could not be applied to aliphatic nitriles, but an indirect method for achieving this conversion is given in **19-60**. α-Dialkylamino nitriles can be converted to ketones, $R_2C(NMe_2)CN \rightarrow R_2C{=}O$, by hydrolysis with $CuSO_4$ in aqueous methanol[451] or by autoxidation in the presence of *t*-BuOK.[452]

C. Reactions Involving Replacement of Hydrogen by Heteroatoms

19-14 Hydroxylation at an Aliphatic Carbon

Hydroxylation or **Hydroxy-de-hydrogenation**

$$R_3CH \xrightarrow[\text{silica gel}]{O_3} R_3COH$$

Compounds containing susceptible C—H bonds can be oxidized to alcohols.[453] Nearly always, the C—H bond involved is tertiary, so the product is a tertiary alcohol. This is partly because tertiary C—H bonds are more susceptible to free-radical attack than primary and secondary bonds and partly because the reagents involved

would oxidize primary and secondary alcohols further. In the best method, the reagent is ozone and the substrate is absorbed on silica gel.[454] Yields as high as 99% have been obtained by this method. Other reagents are chromic acid,[455] potassium hydrogen persulfate ($KHSO_5$),[456] ruthenium tetroxide (RuO_4),[457] 2,6-dichloropyridine *N*-oxide with a ruthenium catalyst,[458] thallium acetate,[459] sodium chlorite ($NaClO_2$) with a metalloporphyrin catalyst,[460] and certain peroxybenzoic acids.[461] Alkanes and cycloalkanes have been oxidized at secondary positions, to a mixture of alcohols and trifluoroacetates, by 30% aq. H_2O_2 in trifluoroacetic acid.[462] This reagent does not oxidize the alcohols further and ketones are not found. As in the case of chlorination with *N*-haloamines and sulfuric acid (see **14-1**), the ω - 1 position is the most favored. Another reagent[463] that oxidizes secondary positions is iodosylbenzene, catalyzed by Fe^{III}–porphyrin catalysts.[464] Use of an optically active Fe^{III}–porphyrin gave enantioselective hydroxylation, with moderate ee.[465]

When chromic acid is the reagent, the mechanism is probably as follows: a Cr^{6+} species abstracts a hydrogen to give R_3C•, which is held in a solvent cage near the resulting Cr^{5+} species. The two species then combine to give R_3COCr^{4+}, which is hydrolyzed to the alcohol. This mechanism predicts retention of configuration; this is largely observed.[466] The oxidation by permanganate also involves predominant retention of configuration, and a similar mechanism has been proposed.[467]

Treatment of double-bond compounds with selenium dioxide introduces an OH group into the allylic position (see also, **19-17**).[468] This reaction also produces conjugated aldehydes in some cases.[469] Allylic rearrangements are common. There is

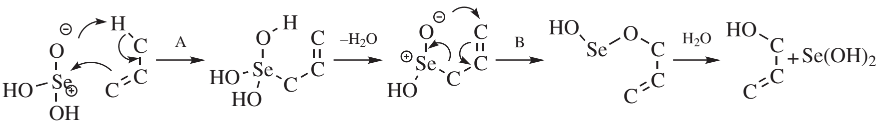
evidence that the mechanism does not involve free radicals, but includes two pericyclic steps (A and B):[470]



The step marked A is similar to the ene synthesis (**15-23**). The step marked B is a [2,3]-sigmatropic rearrangement (see **18-35**). The reaction can also be accomplished with *tert*-butyl hydroperoxide, if SeO_2 is present in catalytic amounts (the *Sharpless method*).[471] The SeO_2 is the actual reagent; the peroxide reoxidizes the $Se(OH)_2$.[472] This method makes work-up easier, but gives significant amounts of side products when the double bond is in a ring.[473] Alkynes generally give α,α'-dihydroxylation.[474]

Ketones and carboxylic esters can be α hydroxylated by treatment of their enolate forms (prepared by adding the ketone or ester to LDA) with a molybdenum peroxide reagent (MoO_5–pyridine–HMPA) in THF–hexane at −70°C.[475] The reaction of ketones with Ti(O*i*Pr)$_4$, diethyl tartrate and *tert*-butylhydroperoxide gave the α-hydroxy ketone with good enantioselectively, albeit in low yield.[476] The enolate forms of amides and esters[477] and the enamine derivatives of ketones[478] can similarly be converted to their α hydroxy derivatives by reaction with molecular oxygen. The MoO_5 method can also be applied to certain nitriles.[479] Ketones have also been α hydroxylated by treating the corresponding silyl enol ethers

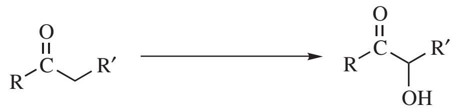
19-15 Oxidation of Methylene to OH, O_2CR, or OR

Hydroxy (or alkoxy) -de-dihydro-bisubstitution



Methyl or methylene groups α to a carbonyl can be oxidized to give α-hydroxy ketones, aldehydes, or carboxylic acid derivatives. Ketones can be α hydroxylated in good yields, without conversion to the enolates, by treatment with the hypervalent iodine reagents[483] *o*-iodosobenzoic acid[484] or phenyliodoso acetate, $PhI(OAc)_2$, in methanolic NaOH.[485] The latter reagent has also been used on carboxylic esters.[486] Dioxygen (O_2) and a chiral phase-transfer catalyst gave enantioselective α-hydroxylation of ketones, if the α position was tertiary.[487] Dimethyl dioxirane is quite effective for hydroxylation of 1,3-dicarbonyl compounds,[488] and O_2 with a manganese catalyst also gives hydroxylation of such compounds.[489] Oxygen with a cerium catalyst α-hydroxylates β-keto esters.[490] Ceric ammonium nitrate has been used to hydroxylate C-2 of dibenzyl malonate.[491] Methyl ketones (RCOMe) react with ammonium peroxydisulfate, $(NH_4)_2S_2O_8$, and a catalytic amount of diphenyl diselenide in MeOH to give α-keto acetals, $RCOCH(OMe_2)$.[492]

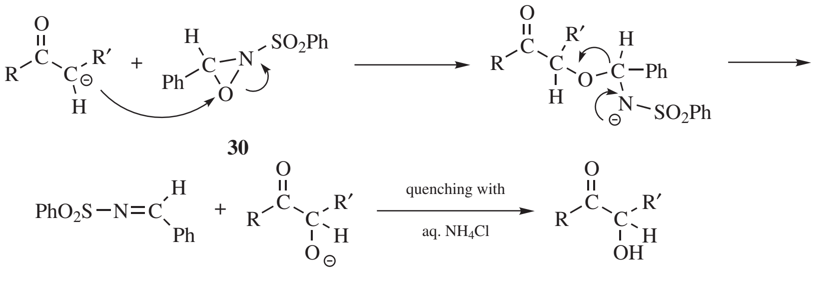
α-Acetoxylation of ketones with concurrent α-arylation occurs when ketones react with $Mn(OAc)_3$ in benzene.[493] α-Acetoxylation of ketones can occur under similar conditions without arylation.[494] α-Methyl ketones are converted to the α-acetoxy derivative under the same conditions.[495] Thallium (III) triflate converts acetophenone to α-formyloxy acetophenone.[496] α-Tosyloxy ketones are generated from acetophenone derivatives using PhI(OH)OTs.[497]

A different method for the conversion of ketones to α-hydroxy ketones consists of treating the enolate anion with a 2-sulfonyloxaziridine (e.g., **30**).[498] This is not a free-radical process; the following mechanism is likely:



30

The method is also successful for carboxylic esters[351],[499] and *N,N*-disubstituted amides,[500] and can be made enantioselective by the use of a chiral oxaziridine.[501] Dimethyldioxirane also oxidizes ketones (through their enolate forms) to α-hydroxy ketones.[502] Titanium enolates can be oxidized with *tert*-butyl hydroperoxide [503] or with dimethyl dioxirane[504] and hydrolyzed with aqueous ammonium fluoride to give the α-hydroxy ketone. Ketones are converted to the α-oxamino derivative ($O{=}C{-}CH_2$- → O=C–CHONHPh) with excellent enantioselectivity using

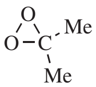
PhN=O and L-proline[505] or (S)-proline.[506] Aldehydes undergo a similar oxidation.[507] α-Lithio sulfones have been hydroxylated with Me_3SiOO*t*-Bu.[508]



Dimethyldioxirane

α-Hydroxyketones can be generated from silyl enol ethers with a catalytic amount of $MeReO_3$ and H_2O_2.[509] Silyl ketene ethers are converted to α-hydroxy esters with H_2O_2 and methyl trioxorhenium.[510] The α′-position of α,β-unsaturated ketones can be selectively oxidized.[511] *N*-Acyl amines are converted to the α-hydroxy derivative with PhIO and a manganese–salen catalyst.[512] Note that homoallylic-type oxidation occurs when an α,α-dimethyl oxime ether is treated with $PhI(OAc)_2$ and a palladium catalyst in acetic acid–acetic anhydride, converting one of the methyl groups to an acetoxymethyl.[513]

Simple alkanes can be converted to esters with dialkyloxiranes. Cyclic alkanes are oxidized to alcohols with dimethyl dioxirane.[514] Cyclohexane was converted to cyclohexyl trifluoroacetate with di(trifluoromethyl) dioxirane and trifluoroacetic anhydride[515] and also with $RuCl_3/MeCO_3H/CF_3CO_2H$.[516] Dimethyl dioxirane converts alkanes to alcohols in some cases.[517] Adamantane is converted to adamantyl alcohol with DDQ (p. 1710) and triflic acid.[518] The mechanism of oxygen insertion into alkanes has been examined.[519]

Benzylic methylene groups are more readily oxidized to benzylic alcohols when compared to simple alkanes. Typical reagents include manganese–salen and PhIO[520] or peroxides.[521] α-Hydroxy ethers are also generated by reaction of this regents with ethers.[522] *N*-Benzyl phthalimide reacts with NBS, NaOAc, and acetic

acid to give *N*-(α-acetoxybenzyl)phthalimide.[523] Methanesulfonic acid and CuO converts ketones to α-mesyloxy (—OMs) ketones[524] and PhI(OH)OTs converts ketones to α-tosyloxy (—OTs) ketones.[525] Aryl methyl carbinols ArCH(OH)Me react with polymer-bound hypervalent iodine complexes, (polymer)–I(OH)OTs, to give a homobenzylic tosylate, $ArCH(OH)CH_2OTs$.[526] Similar oxidation to an acetoxy benzyl derivative was accomplished with $PhI(OAc)_2$ in acetic acid with a palladium catalyst,[527] and with PhI(OH)OTs in aq. DMSO.[528] With minimal water, cerium (IV) triflate converts benzylic arenes to benzylic alcohols, although the major product is the ketone when >15% of water is present.[529]

Allylic hydroxylation[530] with selenium dioxide often gives aldehydes (**19-17**), but in the presence of acetic anhydride and oxygen, SeO_2 converts alkenes to homoallylic acetates as the major product, C=C—C—C → C=C—C—C—OAc.[531] Allylic benzyloxylation occurs when an alkene is treated with *t*-BuOOCOPh and a Cu—Na zeolite,[532] a copper catalyst,[533] or with a chiral copper catalyst to give modest enantioselectivity.[534] Allylic methylene groups can be converted to ester (—CH—OCOR) derivatives in a similar manner using copper triflate.[535] Cupric acetate has also been used,[536] as well as Cu_2O.[537] Acyl peroxides have been used as well.[538] α-Acetoxylation of allylic alkenes can proceed with allylic rearrangement.[539]

Hydroxylation can be accomplished using enzymatic systems. In the presence of *Bacillus megaterium* and oxygen, cyclohexane is converted to cyclohexanol.[540] Allylic oxidation to an allylic alcohol was accomplished with cultured cells of *Gossypium hirsutum*.[541] Benzylic arenes are converted to the corresponding α-hydroxy compound by treatment with the enzymes of *Bacillus megaterium*, with

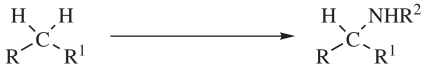
modest enantioselectivity.[542] Cyclic amines react with *Pseudomonas oleovorans* GPol to give hydroxy amines; *N*-benzylpyrrolidine is converted to 3-hydroxy *N*-benzylpyrrolidine.[543] *Sphingomonas* sp. HXN-200 gives similar results.[544] In a similar manner, lactams are converted to the corresponding 3-hydroxy lactam with *sphingomonas* sp. HXN-200.[545] *N*-Benzyl piperidine is converted to the 4-hydroxy derivative under the same conditions. [546] The reaction of tetradecanoic acid with the α-oxidase from *Pisum sativum*, in the presence of molecular oxygen, gives 2(*R*)-hydroxytetradecanoic acid with high asymmetric induction.[547]

19-16 Oxidation of Methylene to Heteroatom Functional Groups Other Than Oxygen or Carbonyl

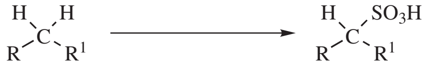
Amino (or amido) -de-dihydro-bisubstitution



α-Amination or amidation of a CH unit is possible in some cases. Cyclic alkanes are converted to the *N*-alkyl *N*-tosylamine with PhI=NTs and a copper complex.[548] Benzylic CH, such as in ethylbenzene, is oxidized with $PhI(OAc)_2$ in the presence of $TsNH_2$ and a fluorinated manganese porphyrin to give the corresponding *N*-tosylamine, PhCHMe(NHTs).[549] Alkenes with an allylic CH react with PhI=NTs and a ruthenium catalysts to give an allylic *N*-tosylamine.[550] When an α-keto ester reacts with DEAD (diethyl azodicarboxylate) and a chiral copper complex, an α- carbamate is formed, $RCH(NHCO_2Et)C(=O)CO_2Et$, with modest enantioselectivity.[551]

Similar reactions are possible, in some cases, to produce sulfur containing compounds.

Sulfo-de-dihydro-bisubstitution



Cyclic alkanes are converted to the corresponding alkylsulfonic acid with SO_2/O_2 and a vanadium catalyst.[552]

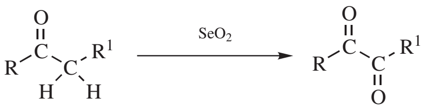
19-17 Oxidation of Methylene to Carbonyl

Oxo-de-dihydro-bisubstitution



Methyl or methylene groups α to a carbonyl can be oxidized with selenium dioxide to give, respectively, α-keto aldehydes (see **19-18**) and α-diketones.[553] The reaction can also be carried out a to an aromatic ring or to a double bond, although in the latter case, hydroxylation (see **19-14**) is the more common result. Selenium dioxide, SeO_2, is the reagent most often used, but the reaction has also been carried out with N_2O_3 and other oxidizing agents,[554] including hypervalent iodine compounds.[555] Sodium nitrite/HCl oxidizes cyclic ketones to the diketone.[556] Substrates most easily oxidized contain two aryl groups on CH_2, and these substrates can be oxidized with many oxidizing agents (see **19-11**). The benzylic position of arenes have been oxidized to alkyl aryl ketones with several oxidizing agents, including CrO_3–acetic acid,[557] the Jones reagent,[558] CrO_3 on silica,[559] pyridinium chlorochromate,[560] DDQ,[561] CrO_2Cl_2 with ultrasound,[562] $KMnO_4$ supported on MnO_2,[563] $KMnO_4$ on alumina with microwave irradiation[564] or on Montmorillonite K10 with either ultrasound or microwave irradiation,[565] $KMnO_4/CuSO_4$ neat[566] or with ultrasound,[567] $NaBrO_3/CeO_2$,[568] manganese–salen/PhIO,[569] *tert*-butylhydroperoxide and a ruthenium catalyst,[570] $Ru(OH)_x$–Al_2O_3 and O_2,[571] hydrogen peroxide with a copper catalyst,[572] as well as with SeO_2. The combination of O_2 and

mcpba oxidizes benzylic arenes to aryl ketones.[573] Note that benzyl methyl ether is oxidized to methyl benzoate with $KMnO_4$ in the presence of benzyltriethylammonium chloride.[574]

Alkenes of the form C=C—CH_2 (an allylic position) have been oxidized to α,β-unsaturated ketones[575] by sodium dichromate in HOAc—Ac_2O, by *t*-BuOOH and chromium compounds,[576] *t*-BuOOH and a palladium catalyst,[577] or a rhodium catalyst,[578] as well as electrolytically.[579] Oxygen, $MeSO_3H$ a palladium catalysts and a molybdobanadophosphate catalyst convert cyclic alkenes to saturated cyclic ketones.[580] Thallium(III) nitrate in aqueous acetic acid converts allylic alkenes to the corresponding saturated ketone, even in the presence of a primary alcohol elsewhere in the molecule.[581] The propargylic position of internal alkynes are oxidized to give propargylic ketones with an iron catalyst,[582] or with O_2/*t*-BuOOH in the presence of $CuCl_2$•H_2O.[583]

Cyclic amines are oxidized to lactams using a mixture of $RuCl_3$ and $NaIO_4$.[584] Lactams are also formed using $KMnO_4$ with benzyltriethylammonium chloride.[585] Tertiary amines are converted to amides[586] and cyclic tertiary amines can be converted to lactams by oxidation with Hg^{II}–EDTA complex in basic solution.[587] Lactams, which need not be *N*-substituted, can be converted to cyclic imides by oxidation with a hydroperoxide or peroxyacid and an Mn(II) or Mn(III) salt.[588] Lactams are oxidized to cyclic imides with oxygen and $Co(OAc)_2$ in the presence *N*-hydroxysuccinimide.[589]

Ethers in which at least one group is primary alkyl can be oxidized to the corresponding carboxylic esters in high yields with ruthenium tetroxide.[590] Molecular

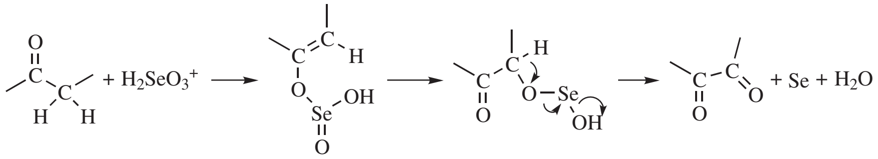
oxygen with a binuclear copperII complex[591] or $PdCl_2/CuCl_2/CO$[592] also converts ethers to esters. In a variation, benzyl *tert*-butyl ethers are oxidized to benzaldehyde derivatives with NO and *N*-hydroxysuccinimide.[593] Cyclic ethers are oxidized to lactones.[594] Cyclic ethers are oxidized to lactones with CrO_3/Me_3SiONO_2.[595] Lactones are also formed from cyclic ethers with $NaBrO_3$–$KHSO_4$ in water.[596]The reaction has also been accomplished with CrO_3 in sulfuric acid,[597] and with benzyltriethylammonium permanganate.[598]

Two mechanisms have been suggested for the reaction with SeO_2. One of these involves a selenate ester of the enol:[599]



In the other proposed mechanism,[600] the principal intermediate is α β-ketoseleninic acid

and a selenate ester is not involved.

It has proved possible to convert CH_2 to C=O groups, even if they are not near any functional groups, indirectly, by the remote oxidation method of Breslow[62] (see **19-2**). In a typical example, the keto ester **31** was irradiated to give the hydroxy lactone **32**, which was dehydrated to **33**. Ozonolysis of **33** gave the diketo ester

31 32 33 34

34, in which the C-14 CH_2 group of **31** has been oxidized to a C=O group.[601] The reaction was not completely regioselective: **34** comprised ~ 60% of the product, with the remainder consisting of other compounds in which the keto group was located at C-12, C-15, and other positions along the carbon chain. Greater regioselectivity was achieved when the aromatic portion was connected to the chain at two positions.[602] In the method so far described, the reaction takes place because one portion of a molecule (the benzophenone moiety) abstracts hydrogen from another portion of the same molecule, that is, the two portions are connected by a series of covalent bonds. However, the reaction can also be carried out where the two reacting centers are actually in different molecules, providing the two molecules are held together by hydrogen bonding. For example, one of the CH_2 groups of *n*-hexadecanol monosuccinate, $CH_3(CH_2)_{14}CH_2OCOCH_2CH_2COOH$, was oxidized to a C=O group by applying the above procedure to a mixture of it and benzophenone-4-carboxylic acid *p*-$PhCOC_6H_4COOH$ in CCl_4.[603]

Other remote oxidations[604] have also been reported. Among these are conversion of aryl ketones $ArCO(CH_2)_3R$ to 1,4-diketones $ArCO(CH_2)_2COR$ by photoirradiation in the presence of such oxidizing agents as $K_2Cr_2O_7$ or $KMnO_4$,[605] and conversion of alkyl ketones, $RCO(CH_2)_3R'$, to 1,3- and 1,4-diketones with $Na_2S_2O_8$ and $FeSO_4$.[606] 2-Octanol was oxidized to give 2-propyl-5-methyl γ-butyrolactone with lead tetraacetate in a CO atmosphere.[607]

It is possible to perform the conversion $CH_2 \rightarrow C{=}O$ on an alkane, with no functional groups at all, although the most success has been achieved with substrates in which all CH_2 groups are equivalent, such as unsubstituted cycloalkanes. One method uses H_2O_2 and bis(picolinato)iron(II). Hydrogen peroxide and trifluoroacetic acid has also been used for oxidation of alkanes.[608] With this method, cyclohexane was converted with 72% efficiency to give 95% cyclohexanone and 5% cyclohexanol.[609] This was also accomplished with $BaRu(O)_2(OH)_3$.[610] The same type of conversion, with lower yields (20–30%), has been achieved with the *Gif system*.[611] There are several variations. One consists of pyridine–acetic acid, with H_2O_2 as oxidizing agent and tris(picolinato)iron(III) as catalyst.[612] Other Gif systems use O_2 as oxidizing agent and zinc as a reductant.[613] The selectivity of the Gif systems toward alkyl carbons is $CH_2 > CH \geq CH_3$, which is unusual, and shows that a simple free-radical mechanism (see p. 942) is not involved.[614] Another reagent that can oxidize the CH_2 of an alkane is methyl(trifluoromethyl)dioxirane, but this produces CH—OH more often than C=O (see **19-14**; **19-15**).[615] Simple unfunctionalized alkanes are oxidized to esters when treated with CBr_4/2 $AlBr_3$ and CO, but in very low yield.[616] Cyclic alkanes are oxidized to a mixture of the alcohol and the ketone with $PhI(OAc)_2$ and a manganese complex in an ionic liquid.[617] Oxidation of cyclic alkanes to cyclic ketones was accomplished using a ruthenium catalyst.[618]

19-18 Oxidation of Arylmethanes to Aldehydes

Oxo-de-dihydro-bisubstitution

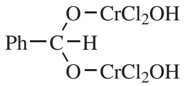
$$ArCH_3 \xrightarrow{CrO_2Cl_2} ArCHO$$

Methyl groups on an aromatic ring can be oxidized to the aldehyde stage by several oxidizing agents. The reaction is a special case of **19-17**. When the reagent is chromyl chloride (CrO_2Cl_2), the reaction is called the *Étard reaction*[619] and the yields are high.[620] Another oxidizing agent is a mixture of CrO_3 and Ac_2O. In this case, the reaction stops at the aldehyde stage because the initial product is $ArCH(OAc)_2$ (an acylal), which is resistant to further oxidation. Hydrolysis of the acylal gives the aldehyde.

Among other oxidizing agents[621] that have been used to accomplish the conversion of $ArCH_3$ to ArCHO are ceric ammonium nitrate,[622] ceric trifluoroacetate,[623] hypervalent iodoso compounds (see **19-3**),[624] urea–H_2O_2 with micrwoave irradiation,[625] and silver(II) oxide.[626] Oxidation of $ArCH_3$ to carboxylic acids is considered at **19-11**.

Conversion of $ArCH_3$ to ArCHO can also be achieved indirectly by bromination to give $ArCHBr_2$ (**14-1**), followed by hydrolysis (**10-2**).

The mechanism of the Étard reaction is not completely known.[627] An insoluble complex is formed on addition of the reagents, which is hydrolyzed to the aldehyde. The complex is probably a kind of acylal, but the identity of the structure is not fully settled, although many proposals have been made as to its structure and as to how it is hydrolyzed.



35

It is known that $ArCH_2Cl$ is not an intermediate (see **19-20**), since it reacts only very slowly with chromyl chloride. Magnetic susceptibility measurements[628]

[619]The name Étard reaction is often applied to any oxidation with chromyl chloride, for example, oxidation of glycols (**19-7**), alkenes (**19-10**), and so on.

indicate that the complex from toluene is **35**, a structure first proposed by Étard. According to this proposal, the reaction stops after only two hydrogens have been replaced because of the insolubility of **35**. There is a disagreement on how **35** is formed, assuming that the complex has this structure. Both an ionic[629] and a free-radical[630] process have been proposed. An entirely different structure for the complex was proposed by Nenitzescu and co-workers.[631] On the basis of esr studies, they proposed that the complex is $PhCH_2OCrCl_2OCrOCl_2OH$, which is isomeric with **35**. However, this view has been challenged by Wiberg and Eisenthal,[336] who interpret the esr result as being in accord with **35**. Still another proposal is that the complex is composed of benzaldehyde coordinated with reduced chromyl chloride.[632]

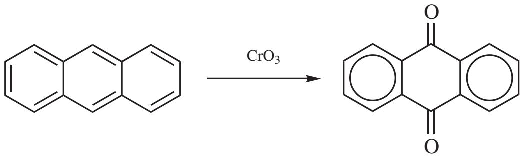
19-19 Oxidation of Aromatic Hydrocarbons to Quinones

Arene-quinone transformation



Condensed aromatic systems (including naphthalenes) can be directly oxidized to quinones by various oxidizing agents.[258,633] Yields are generally not high, although good yields have been reported with ceric ammonium sulfate.[634] Benzene cannot be so oxidized by strong oxidizing agents, but can be electrolytically oxidized to benzoquinone.[635] Naphthalene derivatives, however, are oxidized to naphthoquinones with H_5IO_6 and CrO_3.[636] 1,4-Dimethoxy aromatic compounds are oxidized to para-quinones with an excess of CoF_3 in water–dioxane.[637]

19-20 Oxidation of Primary Halides and Esters of Primary Alcohols to Aldehydes[638]

Oxo-de-hydro, halo-bisubstitution

$$RCH_2Cl \xrightarrow{Me_2SO} RCHO$$

Primary alkyl halides (chlorides, bromides, and iodides) can be oxidized to aldehydes easily and in good yields with dimethyl sulfoxide,[639] in what has been called the *Kornblum reaction*. In Kornblum's original work, the reaction of α-halo ketones with DMSO at elevated temperatures gave good yields of the corresponding glyoxal (an α-keto-aldehyde).[640] If the glyoxal could be removed from the reaction medium by distillation as it was formed, the reaction was very efficient. In many cases, it was difficult to isolate high boiling glyoxals from DMSO. Primary and secondary[641] alkyl iodides or tosylates[642] can be converted to aldehydes or ketones, although they are much less reactive than α-halo ketones. Epoxides[643] have been used to give α-hydroxy ketones or aldehydes.[644] The reaction with tosyl esters is an indirect way of oxidizing primary alcohols to aldehydes (**19-3**). Primary chlorides with DMSO, NaBr, and ZnO give the corresponding aldehyde when heated to 140°C.[645] Primary allylic bromides with a cyano group on the C=C unit are converted to conjugated α-cyano aldehydes with DMSO and $NaHCO_3$ at room temperature.[646]

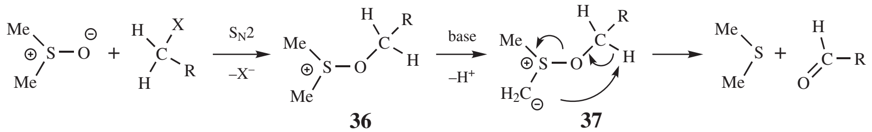
[646]Ravichandran, S. *Synth. Commun.* ***2001***, *31*, 2185.

The mechanism of these DMSO oxidations is probably as follows:[647]



36 37

although in some cases the base abstracts a proton directly from the carbon being oxidized, in which case the ylid **37** is not an intermediate. Alkoxysulfonium salts (**36**) have been isolated.[648] This mechanism predicts that secondary compounds should be oxidizable to ketones, and this is the case. In a related procedure for the oxidation of alcohols, the intermediate **36**[649] is formed without the use of DMSO by treating the substrate with a complex generated from chlorine or NCS and dimethyl sulfide.[650]

Another way to oxidize primary alkyl halides to aldehydes is by the use of hexamethylenetetramine followed by water. However, this reaction, called the *Sommelet reaction*,[651] is limited to benzylic halides. The reaction is seldom useful when the R in RCH_2Cl is alkyl. The first part of the reaction is conversion to the amine $ArCH_2NH_2$, which can be isolated. Reaction of the amine with excess hexamethylenetetramine gives the aldehyde. It is this last step that is the actual Sommelet reaction, although the entire process can be conducted without isolation of intermediates. Once the amine is formed, it is converted to an imine ($ArCH_2N{=}CH_2$) with formaldehyde liberated from the reagent. The key step then follows: transfer of hydrogen from another mole of the arylamine to the imine. This last imine is then hydrolyzed by water to the aldehyde. Alternatively, the benzylamine may transfer hydrogen directly to hexamethylenetetramine. Another method that converts secondary bromides to ketones heads the bromide with $NaIO_4$ in DMF.[652]

Another reagent that convert benzylic halides to aldehydes is pyridine followed by *p*-nitrosodimethylaniline and then water, called the *Kröhnke reaction*. Primary halides and tosylates have been oxidized to aldehydes by trimethylamine *N*-oxide,[653] and by pyridine *N*-oxide with microwave irradiation.[654]

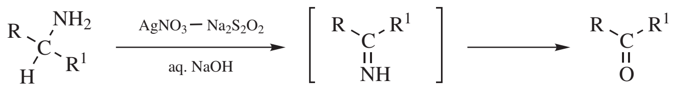
19-21 Oxidation of Amines or Nitro Compounds to Aldehydes, Ketones, or Dihalides

Oxo-de-hydro, amino-bisubstitution (overall transformation)



Primary aliphatic amines can be oxidized to aldehydes or ketones.[656] Other reagents used[657] have been *N*-bromoacetamide[658] (for benzylic amines), 3,5-di-*tert*-butyl-1,2-benzoquinone,[659] and aqueous NaOCl with phase-transfer catalysts.[660] Benzylic amine salts $PhCHRNR'_2\ H^+\ Cl^-$ (R,R′ = H or alkyl) give benzaldehydes or aryl ketones when heated in DMSO.[661] Several indirect methods for achieving the conversion $RR'CHNH_2 \rightarrow RR'C{=}O$ (R′ = alkyl, aryl, or H) have been reported.[662]

Primary, secondary, and tertiary aliphatic amines have been cleaved to give aldehydes, ketones, or carboxylic acids with aqueous bromine[663] and with neutral permanganate.[664] The other product of this reaction is the amine with one less alkyl group. In a different type of procedure, primary alkyl primary amines can be converted to *gem*-dihalides [$RCH_2NH_2 \rightarrow RCHX_2$ (X = Br or Cl)] by treatment with an alkyl nitrite and the anhydrous copper(I) halide.[665]

Primary and secondary aliphatic nitro compounds have been oxidized to aldehydes and ketones, respectively ($RR'CHNO_2 \rightarrow RR'C{=}O$) with sodium chlorite

under phase transfer conditions,[666] tetrapropylammonium perruthenate (TPAP),[667] Oxone®,[668] as well as with other reagents.[669] Vinyl nitro compounds were converted to α-alkylated ketones, with good enantioselectivity, using R_2Zn, a chiral copper catalyst followed by hydrolysis with 20% aqueous sulfuric acid.[670]

19-22 Oxidation of Primary Alcohols to Carboxylic Acids or Carboxylic Esters

Oxo-de-dihydro-bisubstitution

$$RCH_2OH \xrightarrow{CrO_3} RCOOH$$

Primary alcohols can be oxidized to carboxylic acids by many strong oxidizing agents including chromic acid, permanganate,[671] and nitric acid.[672] Other reagents include H_5IO_6/CrO_3.[673] The reaction can be looked on as a combination of **19-3** and **19-23**. When acidic conditions are used, a considerable amount of carboxylic ester $RCOOCH_2R$ is often isolated, although this is probably not formed by a combination of the acid with unreacted alcohol, but by a combination of intermediate aldehyde with unreacted alcohol to give an acetal or hemiacetal, which is oxidized to the ester.[674] Aliphatic primary alcohols are converted to the carboxylic acid with 30% aq. H_2O_2, tetrabutylammonium hydrogen sulfate and a tungsten catalyst with microwave irradiation.[675] Oxone® in DMF also converts aliphatic aldehydes to the corresponding carboxylic acid.[676] Benzylic alcohols are oxidized to benzoic acid derivatives by treatment first with TEMPO[677] (p. 274), and then $NaClO_2$.[678] A combination of $NaClO_2$ and NaH_2PO_4 in aq. DMSO oxidizes aldehydes to acids even in the presence of a disulfide

elsewhere in the molecule.[679] Similar oxidation to the acid occurred with $NaIO_4/RuCl_3$ in aqueous acetonitrile,[680] 30% aq. H_2O_2, and a cobalt–salen catalyst,[681] or oxygen on alumina with microwave irradiation.[682] Aliphatic alcohols are converted to a symmetrical ester ($RCH_2OH \rightarrow RCOOCH_2R$) by oxidation with PCC on aluminum without solvent.[683] Oxone in aqueous methanol also converts aryl aldehydes to the corresponding ester.[684] Allylic alcohols are converted to conjugated esters with MnO_2, NaCN in methanol–acetic acid.[685] Primary alcohols are oxidized to the methyl ester with trichloroisocyanuric acid in methanol.[686] This reagent also converts diols to lactones.

Primary alcohols RCH_2OH can be directly oxidized to acyl fluorides RCOF with cesium fluoroxysulfate.[687] Lactones can be prepared by oxidizing diols in which at least one OH is primary,[688] and addition of a chiral additive, such as sparteine, leads to lactones with high asymmetric induction.[689] 2-(3-Hydroxypropyl)aniline was oxidized to an acyl derivative that cyclized to give a lactam when heated with a rhodium catalyst.[690]

Primary alkyl ethers can be selectively cleaved to carboxylic acids by aq. Br_2 ($RCH_2OR' \rightarrow RCOOH$).[691] Secondary allylic alcohols are converted to ketones with 70% *tert*-butylhydroperoxide with a CrO_3 catalyst.[692]

Oxidation of aldehydes-to-carboxylic acids is quite common[693] and has been carried out with many oxidizing agents, the most popular of which is permanganate in acid, basic, or neutral solution.[694] Chromic acid,[695] bromine, and Oxone®,[696] are other reagents frequently employed. Bromate exchange resin in refluxing acetone oxidizes aryl aldehydes-to aryl-carboxylic acids.[697] Silver oxide is a fairly specific oxidizing agent for aldehydes and does not readily attack other groups. Benedict's and Fehling's solutions oxidize aldehydes,[698] and there is a test for aldehydes that depends on this reaction, but the method is seldom used for preparative purposes. In any case, it gives very poor results with aromatic aldehydes. α,β-Unsaturated aldehydes can be oxidized by sodium chlorite without disturbing the double bond.[699] Aldehydes are also oxidized to carboxylic acids by atmospheric oxygen, but the actual direct oxidation product in this case is the peroxy acid RCO_3H,[700] which with another molecule of aldehyde, disproportionates to give two molecules of acid (see **14-7**).[701] Aryl aldehydes are converted to the corresponding aryl carboxylic ester with hydrogen peroxide and a V_2O_5 catalyst[702] or a titanosilicate[703] in an alcohol solvent. Heating an α-bromoaldhyde with an alcohol and a triazolium carbene leads to the corresponding ester.[704] *N*-Bromophthalimide and mercuric

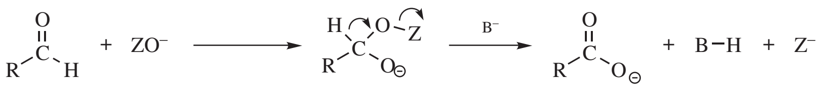
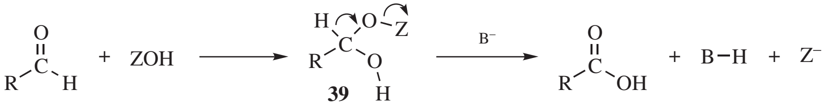
acetate oxidizes aryl aldehydes to aryl carboxylic acids in chloroform at room temperature.[705] An aldehyde can be converted to the carboxylic acid by treatment with 30% hydrogen peroxide and methyl(trioctyl)ammonium hydrogen sulfate at 90°C.[706] Aryl aldehydes are similarly oxidized by a mixture of hydrogen peroxide and selenium dioxide (SeO_2).[707] Aldehydes (RCHO) can be directly converted to carboxylic esters (RCOOR′) by treatment with Br_2 in the presence of an alcohol.[708] Polymer-bound hypervalent iodine + TEMPO oxidizes aldehydes to acids.[709]

Mechanisms of aldehyde oxidation[710] are not firmly established, but there seem to be at least two main types: a free-radical mechanism and an ionic one. In the free-radical process, the aldehydic hydrogen is abstracted to leave an acyl radical, which obtains OH from the oxidizing agent. In the ionic process, the first step is addition of a species $^-$OZ to the carbonyl bond to give **38** in alkaline solution and **39** in acid or neutral solution. The aldehydic hydrogen of **38** or **39** is then lost as a proton to a base, while Z leaves with its electron pair.



38



39

For oxidation with acid dichromate the picture seems to be quite complex, with several processes of both types going on:[711]

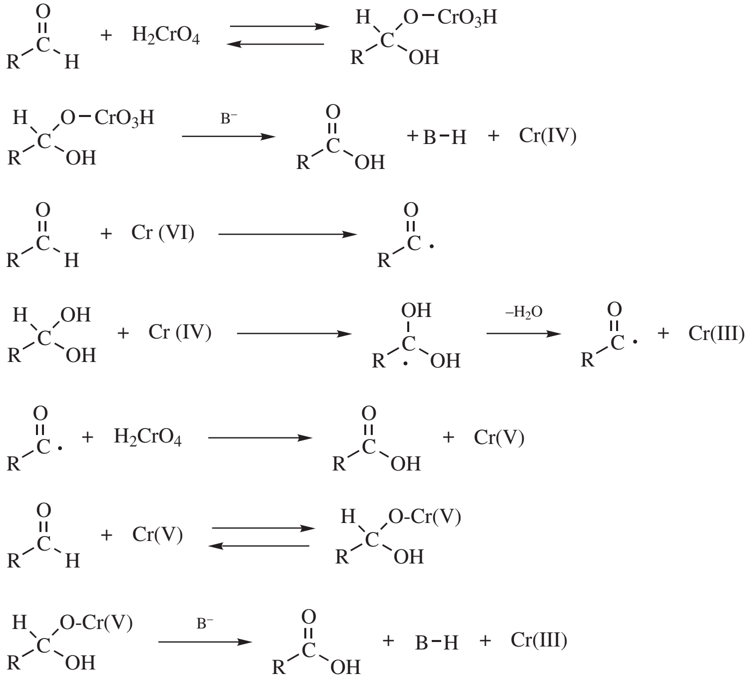
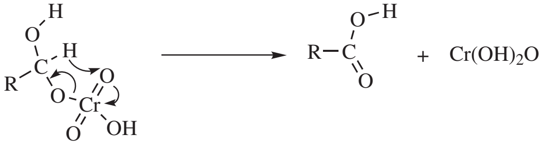
[710]For a review, see Roček, J., in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, ***1966***, pp. 461–505.

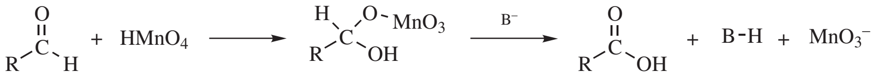
[711]Wiberg, K.B.; Szeimies, G. *J. Am. Chem. Soc.* ***1974***, *96*, 1889. See also, Roček, J.; Ng, C. *J. Am. Chem. Soc.* ***1974***, *96*, 1522, 2840; Sen Gupta, S.; Dey, S.; Sen Gupta, K.K. *Tetrahedron* ***1990***, *46*, 2431.



Steps 1 and 2 constitute an oxidation by the ionic pathway by Cr(VI), and steps 6 and 7 a similar oxidation by Cr(V), which is produced by an electron-transfer process. Either Cr(VI) (step 3) or Cr(IV) (step 4) [Cr(IV) is produced in step 2] may abstract a hydrogen and the resulting acyl radical is converted to carboxylic acid in step 5. Thus, chromium in three oxidation states is instrumental in oxidizing aldehydes. Still another possible process has been proposed in which the chromic acid ester decomposes as follows:[712]



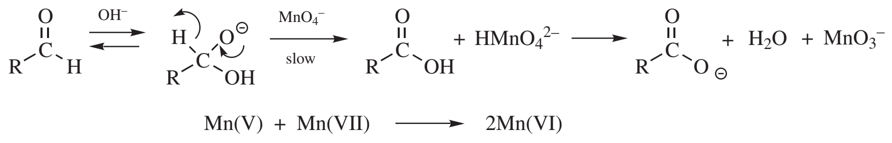
The mechanism with permanganate is less well known, but an ionic mechanism has been proposed[713] for neutral and acid permanganate, similar to steps 1 and 2 for dichromate:



[712]See Roček, J.; Ng, C. *J. Org. Chem.* ***1973***, *38*, 3348.

[713]See, for example, Freeman, F.; Lin, D.K.; Moore, G.R. *J. Org. Chem.* ***1982***, *47*, 56; Jain, A.L.; Banerji, K.K. *J. Chem. Res. (S)* ***1983***, 60.

For alkaline permanganate, the following mechanism has been proposed:[714]

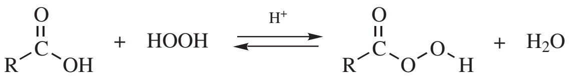


OS **I**, 166; **II**, 302, 315, 538; **III**, 745; **IV**, 302, 493, 499, 919, 972, 974.

The conversion of thioketones to sulfines ($R_2C{=}S{=}O$) is difficult to categorize into the sections available, and it placed after oxidation of ketones and aldehydes. The reaction of a thioketone with hydrogen peroxide and a catalytic amount of MTO (methyl trioxorhenium) gives the sulfine.[715]

19-24 Oxidation of Carboxylic Acids to Peroxy Acids

Peroxy-de-hydroxy-substitution



The oxidation of carboxylic acids with H_2O_2 and an acid catalyst is the best general method for the preparation of peroxy acids.[716] A mixture of $Me_2C(OMe)OOH$ and DCC has also been used.[717] The most common catalyst for aliphatic R is concentrated sulfuric acid. The reaction is an equilibrium and is driven to the right by removal of water or by the use of excess reagents. For aromatic R, the best catalyst is methanesulfonic acid, which is also used as the solvent.

D. Reactions in Which Oxygen is Added to the Substrate

19-25 Oxidation of Alkenes to Aldehydes and Ketones

1/Oxo-(1/→2/hydro)-*migro*-attachment

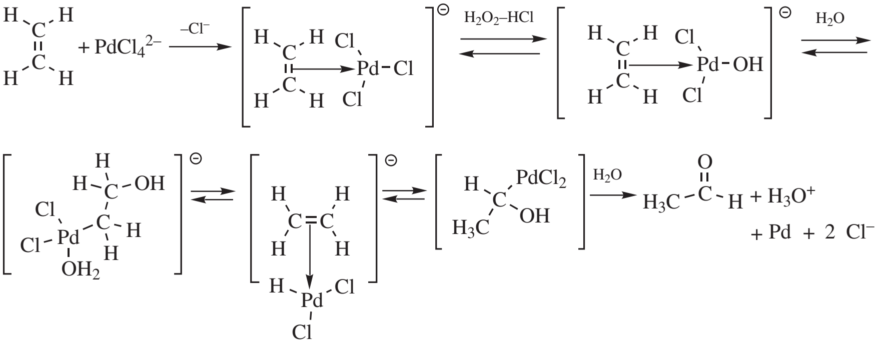
Monosubstituted and 1,2-disubstituted alkenes can be oxidized to aldehydes and ketones by palladium chloride and similar salts of noble metals.[718] 1,1-Disubstituted alkenes generally give poor results. The reaction is used industrially to prepare acetaldehyde from ethylene (the *Wacker process*), but it is also suitable for laboratory preparations. The palladium chloride is reduced to palladium. Because the reagent is expensive, the reaction is usually carried out with a co-oxidant, most often $CuCl_2$, whose function is to reoxidize the Pd to Pd(II). The $CuCl_2$ is reduced to Cu(I), which itself is reoxidized to Cu(II) by air, so that atmospheric oxygen is the only oxidizing agent actually used up. Many other co-oxidants have been tried, among them O_3, Fe^{3+}, and PbO_2. Terminal alkenes are oxidized to methyl ketones with O_2 and a palladium catalyst with 20% pyridine in Z-propanol.[719] *tert*-Butylhydroperoxide in bromoperfluorooctane–benzene oxidizes styrene to acetophenone in a Wacker-type process.[720] The principal product is an aldehyde only from ethylene: With other alkenes Markovnikov's rule is followed, and ketones are formed predominantly.

The generally accepted mechanism involves π complexes of palladium.[721]



This mechanism accounts for the fact, established by deuterium labeling, that the four hydrogens of the acetaldehyde all come from the original ethylene and none from the solvent.

Similar reactions have been carried out with other oxidizing agents. An example involving migration of an alkyl group instead of hydrogen is oxidation of $Me_2C{=}CMe_2$ with peroxytrifluoroacetic acid-boron trifluoride to give Me_3COMe (pinacolone).[722] This reaction consists of epoxidation (**15-50**) followed by pinacol rearrangement of the epoxide (**18-2**). A migration is also involved in the conversion of $ArCH{=}CHCH_3$ to $ArCH(CH_3)CHO$ by treatment with I_2-Ag_2O in aqueous dioxane.[723]

Other reagents used have been $Pb(OAc)_4$–F_3CCOOH[724] (e.g., $PhCH{=}CH_2 \rightarrow PhCH_2CHO$), H_2O_2 and a Pd catalyst,[725] H_2O–$PdCl_2$–polyethylene glycol,[726] CrO_3–H_2SO_4–Hg(II) salts,[727] and $Hg(OAc)_2$ followed by $PdCl_2$.[728] The reaction has also been accomplished electrochemically.[729] Terminal alkenes react with ceric ammonium nitrate in methanol to give α-methoxy ketones.[730]

Alkenes have also been converted to more highly oxidized products. Examples are (*1*) treatment with $KMnO_4$ in aqueous acetone containing acetic acid gives α-hydroxy ketones.[731] (*2*) 1,2-Disubstituted and trisubstituted alkenes give α-chloro ketones when oxidized with chromyl chloride in acetone: $RCH{=}CR'R^2 \rightarrow RCOCClR'R^2$.[732] (*3*) α-Iodo ketones can be prepared by treating alkenes with bis-(*sym*-collidine)iodine(I) tetrafluoroborate.[733] (*4*) potassium permanganate in acetic anhydride oxidizes large-ring cycloalkenes to 1,2-diketones.[734]

Enol ethers are oxidized to carboxylic esters ($RCH{=}CHOR' \rightarrow RCH_2COOR'$) with PCC[735] and enamines to α-amino ketones ($R^1CH{=}CR_2NR \rightarrow R^1COCR_2NR$) with *N*-sulfonyloxaziridines.[736] Enamines ($R^1R^4C{=}CR^2NR^3_2$, $R^4 \neq H$) do not give these products, but lose the amino group to give α-hydroxy ketones, $R^1R^4C(OH)$-COR^2.[736] Carboxylic acids can be prepared from terminal alkynes ($RC{\equiv}CH \rightarrow$

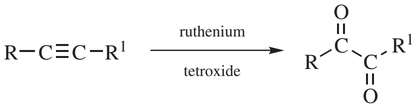
19-26 The Oxidation of Alkynes to α-Diketones

Dioxo-biaddition



Internal alkynes have been oxidized[738] to α-diketones by several oxidizing agents,[739] including neutral $KMnO_4$,[740] bis(trifluoroacetoxy)iodobenzene,[741] $NaIO_4$–RuO_2,[742] I_2–DMSO,[743] $MeReO_3/H_2O_2$,[744] as well as by electrooxidation.[745] A ruthenium complex with a small amount of trifluoroacetic acid converts internal alkynes to the α-diketone.[746] Ozone generally oxidizes triple-bond compounds to carboxylic acids (**19-9**), but α-diketones are sometimes obtained instead. Selenium dioxide (SeO_2) with a small amount of H_2SO_4 oxidizes alkynes to α-diketones as well as arylacetylenes to α-keto acids (ArC≡CH → ArCOCOOH).[747]

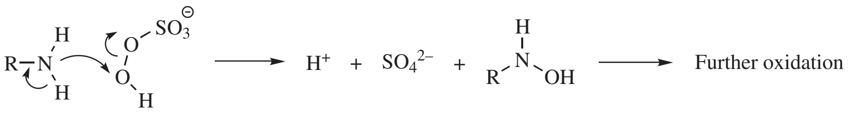
Primary aromatic amines can be oxidized[748] to nitroso compounds. Most often the conversion is accomplished by Caro's acid (H_2SO_5) or with H_2O_2 in HOAc.[749] Hydroxylamines, which are probably intermediates in most cases, can sometimes be isolated, but under the reaction conditions are generally oxidized to the nitroso compounds. Primary aliphatic amines can be oxidized in this manner, but the nitroso compound is stable only if there is no α hydrogen. If there is an α hydrogen, the compound tautomerizes to the oxime.[750] Among the reagents used for this oxidation are sodium perborate[751] H_2O_2 with a titanium complex,[752] HOF generated *in situ*,[753] and Na_2WO_4/H_2O_2.[754] The mechanism with H_2SO_5 has been postulated to be an example of category 5 (p. 1706).[755]



Secondary amines, R_2NH, are oxidized to hydroxylamines (R_2NHOH) which are resistant to further oxidation, by dimethyldioxirane[756] and by benzoyl peroxide and Na_2HPO_4.[757] Oxone® on silica also oxidizes secondary alcohols to the hydroxylamine.[758] Hydroxylamines are formed when secondary amines react with the enzyme cyclohexanone monooxygenase.[759] Carbamates, such as *N*-Boc amines, are converted tot he *N*-hydroxy compound with bis(trifluoromethyl)-dioxirane.[760] Note that secondary alcohols can be converted to nitrones with aq. H_2O_2 and a phosphotungstate polymer complex, presumably via an hydroxylamine (see **19-28**) formed *in situ*.[761] Dialkylamiens are oxidized to the *N*-nitroso compound with N_2O_2 on polyvinylpyrrolidinone.[762]

19-28 Oxidation of Primary Amines, Oximes, Azides, Isocyanates, or Nitroso Compounds to Nitro Compounds

$$R_3CNH_2 \xrightarrow{KMnO_4} R_3CNO_2$$

$$R_2C{=}NOH \xrightarrow{F_3CCOOOH} R_2CHNO_2$$

Tertiary alkyl primary amines can be oxidized to nitro compounds in excellent yields with $KMnO_4$.[763] This type of nitro compound is not easily prepared in other ways. All classes of primary amine (including primary, secondary, and tertiary alkyl, as well as aryl) are oxidized to nitro compounds in high yields with dimethyldioxirane.[764] Other reagents that oxidize various types of primary amines to nitro compounds are dry ozone,[765] various peroxyacids,[766] $MeReO_3/H_2O_2$,[767] Oxone®,[768] *tert*-butyl hydroperoxide in the presence of certain molybdenum and vanadium compounds,[769] and sodium perborate.[770]

Dimethyldioxirane in wet acetone oxidizes isocyanates to nitro compounds ($RNCO \rightarrow RNO_2$).[771] Oximes can be oxidized to nitro compounds with peroxytrifluoroacetic acid, or Oxone®,[772] sodium perborate,[773] among other ways.[763] Secondary hydroxylamines are also oxidized to nitrones with MnO_2 in dichloromethane.[774] Primary and secondary alkyl azides have been converted to nitro compounds by treatment with Ph_3P followed by ozone.[775] Aromatic nitroso compounds are easily oxidized to nitro compounds by many oxidizing agents.[776]

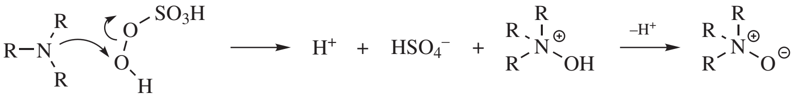
19-29 Oxidation of Tertiary Amines to Amine Oxides

N-Oxygen-attachment

Tertiary amines can be converted to amine oxides by oxidation. Hydrogen peroxide is often used, but peroxyacids are also important reagents for this purpose. Pyridine and its derivatives are oxidized by peroxyacids[777] rather than hydrogen peroxide. Note, however, that urea–H_2O_2 in formic acid does indeed oxidize pyridine.[778] In the attack by hydrogen peroxide there is first formed a trialkylammonium peroxide, a hydrogen-bonded complex represented as $R_3N{\bullet}H_2O_2$, which can be isolated.[779] The decomposition of this complex probably involves an attack by the OH moiety of the H_2O_2. Oxidation with Caro's acid has been shown to proceed in this manner:[780]



This mechanism is the same as that of **19-27**; the products differ only because tertiary amine oxides cannot be further oxidized. The mechanism with other peroxyacids is probably the same. A green procedure for oxidation of tertiary amines has been developed, using a Mg–Al complex with aq. hydrogen peroxide.[781]

An alternative oxidation using O_2 and a $RuCl_3$ catalyst converted pyridine to pyridine *N*-oxide.[782] Bromamine-T and $RuCl_3$ in aq. acetonitrile also oxidizes pyridine to the *N*-oxide.[783] Tertiary amines are oxidized to the *N*-oxide with O_2 and Fe_2O_3 in the presence of an aliphatic aldehyde.[784] Oxygen and a cobalt–Schiff base complex also oxidzes tertiary amines, including pyridine.[785]

It is noted that azo compounds can be oxidized to azoxy compounds by peroxyacids[786] or by hydroperoxides and molybdenum complexes.[787]

Analogous to the oxidation of tertiary amines, tertiary phosphines are oxidized to phosphine oxides, ($R_3P{=}O$). Triphenylphosphine is converted to triphenylphosphine

19-30 Oxidation of Thiols and Other Sulfur Compounds to Sulfonic Acids

Thiol-sulfonic acid oxidation

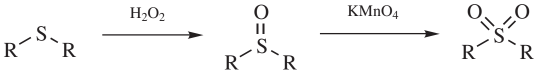
$$RSH \xrightarrow{HNO_3} RSO_3H$$

Thiols, sulfoxides, sulfones, disulfides,[790] and other sulfur compounds can be oxidized to sulfonic acids with many oxidizing agents, but for synthetic purposes the reaction is most important for thiols.[791] Among oxidizing agents used are boiling nitric acid, barium permanganate, and dimethyl dioxirane.[792] Autoxidation (oxidation by atmospheric oxygen) can be accomplished in basic solution.[793] Oxidation of thiols with chlorine and water gives sulfonyl chlorides directly.[794] Thiols can also be oxidized to disulfides (**19-34**).

OS **II**, 471; **III**, 226. Also see, OS **V**, 1070.

19-31 Oxidation of Thioethers to Sulfoxides and Sulfones

S-Oxygen-attachment



Thioethers can be oxidized to sulfoxides by 1 equivalent of 30% H_2O_2 or by many other oxidizing agents,[795] including H_2O_2–flavin catalyst,[796] H_2O_2 and a

oxidation to sulfoxides with an optically active reagent, and this has often been done.[822] In addition, the use of chiral additives in conjunction with various oxidizing agents leads to chiral nonracemic sulfoxide with good-to-excellent enantioselectivity.[823] Asymmetric oxidation using bacterial monooxygenases is known,[824] and horseradish peroxidase gives modest enantioselectivity.[825] Chiral sulfur reagents are also known.[826] Selenides (R_2Se) can be oxidized to selenoxides and selenones.[827] It is possible to oxidize a thioether to a sulfoxide in the presence of an alcohol moiety using MnO_2/HCl.[828] Alkyl disulfides give oxidation of one sulfur to give a (RS—S(=O)R compound with good enantioselectivity when using aqueous hydrogen peroxide, a catalytic amount of a vanadium catalyst and a chiral Schiff base ligand.[829] *N*-Sulfonyloxaziridines can be used to oxidize sulfides to sulfoxides.[830]

When the oxidizing agent is a peroxide, the mechanism[831] of oxidation to the sulfoxide is similar to that of **19-29**.[832]

The second oxidation, which is normally slower than the first[833] (which is why sulfoxides are so easily isolable), has the same mechanism in neutral or acid solution, but in basic solution it has been shown that the conjugate base of the peroxy compound ($R'OO^-$) also attacks the SO group as a nucleophile:[834]

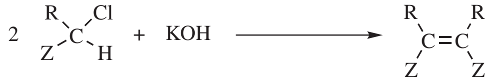
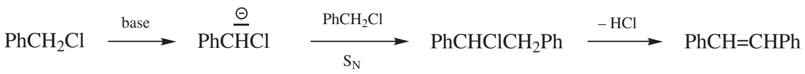
E. Oxidative Coupling

19-32 Coupling Involving Carbanions

De-hydro,chloro-coupling



Alkyl halides with an electron-withdrawing group on the halogen-bearing carbon can be dimerized to alkenes by treatment with bases. The Z group may be nitro, aryl, and so on. It is likely that in most cases the mechanism[835] involves nucleophilic substitution followed by elimination[836] (illustrated for benzyl chloride):



α,α-Dibromotoluenes ($ArCHBr_2$) give tolanes ArC≡CAr), by debromination of the intermediates ArCBr=CBrAr.[837] In a related reaction, diarylmethane dihalides

[833]There are some reagents that oxidize sulfoxides in preference to sulfides, for example, NaMnO4: see Henbest, H.B.; Khan, S.A. *Chem. Commun.* ***1968***, 1036.

[834]Curci, R.; Di Furia, F.; Modena, G. *J. Chem. Soc. Perkin Trans. 2* ***1978***, 603, and references cited therein. See also, Oae, S.; Takata, T. *Tetrahedron Lett.* ***1980***, *21*, 3213; Akasaka, T.; Ando, W. *J. Chem. Soc. Chem. Commun.* ***1983***, 1203.

[835]For discussion, see Saunders, Jr., W.H.; Cockerill, A.F. *Mechanisms of Elimination Reactions*, Wiley, NY, ***1973***, pp. 548–554.

[836]For example, see Hauser, C.R.; Brasen, W.R.; Skell, P.S.; Kantor, S.W.; Brodhag, A.E. *J. Am. Chem. Soc.* ***1956***, *78*, 1653; Hoeg, D.F.; Lusk, D.I. *J. Organomet. In some cases, a radical anion chain mechanism can take place: Bethell, D.; Bird, R. *J. Chem. Soc. Perkin Trans. 2* ***1977***, 1856.

[837]Vernigor, E.M.; Shalaev, V.K.; Luk'yanets, E.A. *J. Org. Chem. USSR* ***1981***, *17*, 317.

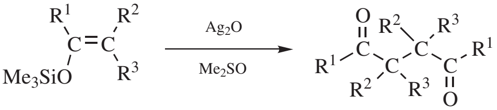
(Ar_2CX_2) have been dimerized to tetraaryl alkenes ($Ar_2C{=}CAr_2$) with copper,[838] and with iron(II) oxalate dihydrate.[839]

A somewhat different type of coupling is observed when salts of β-keto esters, arylacetonitriles ($ArCH_2CN$), and other compounds of the form ZCH_2Z' are treated with an oxidizing agent, such as iodine,[840] or Cu(II) salts.[841] Arylmethanesulfonyl chlorides ($ArCH_2SO_2Cl$) couple to give ArCH=CHAr when treated with Et_3N.[842]

OS **II**, 273; **IV**, 372, 869, 914; **VIII**, 298. Also see, OS **I**, 46; **IV**, 877.

19-33 Dimerization of Silyl Enol Ethers or of Lithium Enolates

3/*O*-De-trimethylsilyl-1/*C*-coupling



40

Silyl enol ethers can be dimerized to symmetrical 1,4-diketones by treatment with Ag_2O in DMSO or certain other polar aprotic solvents.[843] The reaction has been performed with R^2, R^3 = hydrogen or alkyl, although best yields are obtained when $R^2 = R^3 = H$. In certain cases, unsymmetrical 1,4-diketones have been prepared by using a mixture of two silyl enol ethers. Other reagents that have been used to achieve either symmetrical or cross-coupled products are iodosobenzene–BF_3–Et_2O,[844] ceric ammonium nitrate,[845] and lead tetraacetate.[846] If R^1 = OR (in which case the substrate is a ketene silyl acetal), dimerization with $TiCl_4$ leads to a dialkyl succinate (**40**, R^1 = OR).[847]

In a similar reaction, lithium enolates, RC(OLi)=CH_2, were dimerized to 1,4-diketones ($RCOCH_2CH_2COR$) with $CuCl_2$, $FeCl_3$, or copper(II) triflate, in a nonprotic solvent.[848]

19-34 Oxidation of Thiols to Disulfides

***S*-De-hydrogen-coupling**

$$2\ \mathrm{RSH} \xrightarrow{H_2O_2} \mathrm{RSSR}$$

Thiols are easily oxidized to disulfides.[849] Hydrogen peroxide is the most common reagent,[850] but many oxidizing agents give the reaction, among them $KMnO_4$/$CuSO_4$,[851] Me_2SO—I_2,[852] Br_2 under phase-transfer conditions,[853] Br_2 on hydrated silica,[854] sodium perborate,[855] NaI/air,[856] *t*-BuOOH/VO(acac)$_2$,[857] SmI_2,[858] PPh_3 with a rhodium catalyst,[859] dibromohydantoin,[860] cetyltrimethylammonium dichromate,[861] and NO. It can also be done electrochemically.[862] Hydrogen peroxide 30% in hexafluoroisopropanol converts thiols to disulfides,[863] on Clayan with microwave irradiation,[864] and solventless reactions on MnO_2,[865] PCC (p. 1716)[866] or SO_2Cl_2[867] are also effective. However, strong oxidizing agents may give **19-26**. Even the oxygen in the air oxidizes thiols on standing, if a small amount of base is present. The reaction is reversible (see **19-75**), and the interconversion between cysteine and cystine is an important one in biochemistry.

[849]For a review, see Capozzi, G.; Modena, G., in Patai, S. *The Chemistry of the Thiol Group*, pt. 2, Wiley, NY, ***1974***, pp. 785–839. For a list of reagents, with references, see Block, E. *Reactions of Organosulfur Compounds*, Academic Press, NY, ***1978***.

[850]It has been pointed out that, nevertheless, H2O2 is not a very good reagent for this reaction, since it gives sulfonic acids (**19-30**) as well as disulfides: Evans, B.J.; Doi, J.T.; Musker, W.K. *J. Org. Chem.* ***1990***, *55*, 2337.

[867]Leino, R.; Lönnqvist, J.-E. *Tetrahedron Lett.* ***2004***, *45*, 8489.

The mechanism has been studied for several oxidizing agents and varies with the agent.[868] For oxygen it is[869]

$$RSH + B^- \rightleftharpoons RS^- + BH$$
$$RS^- + O_2 \longrightarrow RS\bullet + \bullet O_2^-$$
$$RS^- + \bullet O_2^- \longrightarrow RS\bullet + O_2^{2-}$$
$$2\ O_2^{2-} + 2\ BH \longrightarrow 2\ OH^- + 2\ B^- + O_2$$

With respect to the sulfur, this mechanism is similar to that of **14-16**, involving as it does loss of a proton, oxidation to a free radical, and radical coupling.

Unsymmetrical disulfides can be prepared[870] by treatment of a thiol RSH with diethyl azodicarboxylate EtOOCN=NCOOEt to give an adduct, to which another thiol R′SH is then added, producing the disulfide RSSR′.[871]

OS **III**, 86, 116.

REDUCTIONS

For the most part, reductions have been grouped into this chapter, with a few notable exceptions. Catalytic hydrogenation of alkenes and alkynes in **15-11** and **15-12**, hydrogenation of aromatic rings in **15-13** and reductive cleavage of cyclopropanes in **15-15** were placed in Chapter 15 to coincide with addition reactions, and protonolysis of alkyl boranes in **15-16** was placed there also for continuity. In general, reductions of functional groups encompass a variety of reaction types. The reactions in this section are classified into groups depending on the type of bond change involved. These groups are (*1*) attack at carbon (C—O and C=O), (*2*) attack at non-carbonyl multiple bonds to heteroatoms, (*3*) reactions in which a heteroatom is removed from the substrate, (*4*) reduction with cleavage, (*5*) reductive coupling, and (*6*) reactions in which an organic substrate is both oxidized and reduced. Most of the reagents in this section are metal hydrides, metals with an acid or a protic solvent, hydrogen gas with a catalyst, and so on. Other reducing agents are available, and will be introduced in the appropriate section. Note that plants can be used as reducing agents.[872]

TABLE 19.2. The Ease of Reduction of Various Functional Groups Toward Catalytic Hydrogenation.[876]

Reaction	Substrate[a]	Product	
19-39	RCOCl	RCHO	Easiest
19-45	RNO_2	RNH_2	
15-11	RC≡CR	RCH=CHR	
19-36	RCHO	RCH_2OH	
15-11	RCH=CHR	RCH_2CH_2R	
19-36	RCOR	RCHOHR	
19-56	$ArCH_2OR$	$ArCH_3$ + ROH	
19-43	RC≡N	RCH_2NH_2	
15-14			
19-38	RCOOR′	RCH_2OH + R′OH	
19-64	RCOHNR′	RCH_2NHR	
15-13			Most difficult
19-37	$RCOO^-$		Inert

[a]The groups are listed in approximate order of ease of reduction.

Selectivity[873]

It is often necessary to reduce one group in a molecule without affecting another reducible group. It is usually possible to find a reducing agent that will do this. The most common broad-spectrum reducing agents are the metal hydrides[874] and hydrogen (with a catalyst).[875] Many different metal-hydride systems and hydrogenation catalysts have been investigated in order to find conditions under which a given group will be reduced chemoselectively. Tables 19.2–19.4 list the reactivity of various functional groups toward catalytic hydrogenation, $LiAlH_4$, and BH_3, respectively.[876]

19-43	RC≡N	RCH_2NH_2	
19-45	RNO_2	RNH_2	
19-80	$ArNO_2$	ArN=NAr	Most difficult
15-11	$RCH{=}CHR^-$		Inert

[a]However, $LiAlH_4$ is a very powerful reagent, and much less chemoselectivity is possible here than with most of the other metal hydrides.

Table 19.5 shows which groups can be reduced by catalytic hydrogenation and various metal hydrides.[877] Of course, the tables cannot be exact, because the nature of R and the reaction conditions obviously affect reactivity. Nevertheless, the tables do give a fairly good indication of which reagents reduce which

TABLE 19.4. The Ease of Reduction of Various Functional Groups With Borane[876]

Reaction	Substrate[a]	Product	
19-37	RCOOH	RCH_2OH	Easiest
15-16	RCH=CHR	$(RCH_2CHR)_3B$	
19-36	RCOR	RCHOHR	
19-43	RCN	RCH_2NH_2	
19-35		RCH_2CHOHR	
19-38	RCOOR′	$RCH_2OH + R'OH$	Most difficult
19-39,19-63	RCOCl		Inert

[a]It is evident that this reagent and $LiAlH_4$ (Table 19.3) complement each other.

[877]The first 10 columns are from Brown, H.C.; Krishnamurthy, S. *Tetrahedron* ***1979***, *35*, 567, p. 604. The column on (*i*-Bu)2AlH is from Yoon, N.M.; Gyoung, Y.S. *J. Org. Chem.* ***1985***, *50*, 2443; the one on NaAlEt2H2 from Stinson, S.R. *Chem. Eng. News, Nov. 3*, ***1980***, *58*, No. 44, 19; and the one on LiBEt3H from Brown, H.C.; Kim, S.C.; Krishnamurthy, S. *J. Org. Chem.* ***1980***, *45*, 1. For similar tables that show additional reducting agents, see Pelter, A.; Smith, K.; Brown, H.C. *Borane Reagents*, Academic Press, NY, ***1988***, p. 129; Hajós, A. *Complex Hydrides*, Elsevier, NY, ***1979***, pp. 16–17. For tables showing which agents reduce a wide variety of functional groups, see Hudlický, M. *Reductions in Organic Chemistry*, Wiley, NY, ***1984***, pp. 177–200.

groups.[878] Lithium aluminium hydride is a very powerful and unselective reagent.[879] Consequently, other metal hydrides are generally used when chemoselectivity is required. As will be seen on p. 1794, a number of less reactive (and more selective) reagents have been prepared by replacing some of the hydrogens of $LiAlH_4$ with alkoxy groups (by treatment of $LiAlH_4$ with ROH).[880] Most of the metal hydrides are nucleophilic reagents and attack the carbon atom of a carbon-hetero single or multiple bond. Another useful reagent is LiAlHSeH.[881] However, BH_3[882,883] and AlH_3[884] are electrophiles (Lewis acids) and attack the heteroatom. This accounts for the different patterns of selectivity shown in the tables.

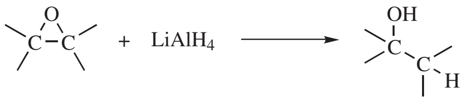
19-35 Reduction of Epoxides

(3)*OC-seco*-Hydro-de-alkoxylation



Reduction of epoxides is a special case of **19-56** and is easily carried out.[891] The most common reagent is $LiAlH_4$,[892] which reacts by the S_N2-type mechanism, giving inversion of configuration. An epoxide on a substituted cyclohexane ring cleaves in such a direction as to give an axial alcohol. As expected for an S_N2 mechanism, cleavage usually occurs so that a tertiary alcohol is formed if possible. If not, a secondary alcohol is preferred. However, for certain substrates, the epoxide ring can be opened the other way by reduction with $NaBH_4$–$ZrCl_4$,[893] Pd/C and

[890]Reduced to hydroxylamine (**19-46**).

[892]See Healy, E.F.; Lewis, J.D.; Minniear, A.B. *Tetrahedron Lett.* ***1994***, *35*, 6647 for a discussion of the LiAlH4 reduction of unsaturated cyclic epoxides.

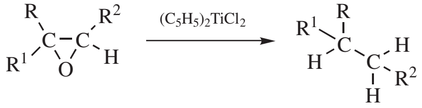
[893]Laxmi, Y.R.S.; Iyengar, D.S. *Synth. Commun.* ***1997***, *27*, 1731 (addition of L-proline to this reaction leads to moderate asymmetric induction).

$HCOONH_4$,[894] SiO_2–$Zn(BH_4)_2$,[895] or with BH_3 in THF.[896] The reaction has also been carried out with other reagents, for example, sodium amalgam in EtOH, Li in ethylenediamine,[897] Bu_3SnH–NaI,[898] and by catalytic hydrogenolysis.[899] Chemoselective and regioselective ring opening (e.g., of allylic epoxides and of epoxy ketones and esters) has been achieved with SmI_2,[900] HCOOH–NEt_3 and a palladium catalyst,[901] and sodium bis(2-methoxyethoxy)aluminum hydride (Red-Al).[902] Highly hindered epoxides can be conveniently reduced, without rearrangement, with lithium triethylborohydride.[903]

Epoxy ketones are selectively reduced with lithium naphthalenide[904] or Cp_2TiCl in THF/MeOH[905] to the β-hydroxyketone. Other reduction methods can lead to the epoxy alcohol (see p.$$$). Reduction of epoxy amides with SmI_2 in methanol gave the α-hydroxyamide.[906]

Epi-sulfides can be reduced to give the alkene using Bu_3SnH in the presence of BEt_3.[907]

Epoxides can be reductively halogenated (the product is the alkyl bromide or iodide rather than the alcohol) with Me_3SiCl–NaX–$(Me_2SiH)_2O$ (1,1,3,3-tetramethyldisiloxane).[908]



The usual product of epoxide reductions is the alcohol, but epoxides are reduced all the way to the alkane by titanocene dichloride[909] and by Et_3SiH–BH_3.[910]

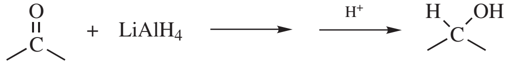
19-36 Reduction of Aldehydes and Ketones to Alcohols[911]

C,O-Dihydro-addition



Aldehydes can be reduced to primary alcohols, and ketones to secondary alcohols, by a number of reducing agents,[912] of which $LiAlH_4$ and other metallic hydrides are the most commonly used.[913] These reagents have two main advantages over many other reducing agents: They do not reduce carbon–carbon double or triple bonds (with the exception of propargylic alcohols),[914] and with $LiAlH_4$ all four hydrogens are usable for reduction. The reaction is broad and general. Lithium aluminum hydride easily reduces aliphatic, aromatic, alicyclic, and heterocyclic aldehydes, containing double or triple bonds and/or nonreducible groups, such as NR_3, OH, OR, and F. If the molecule contains a group reducible by $LiAlH_4$ (e.g., NO_2, CN, COOR), then it is also reduced. Since $LiAlH_4$ reacts readily with water and alcohols, these compounds must be excluded. Common solvents are ether and THF. The compound $NaBH_4$ has a similar scope, but is more selective and so may be used with NO_2, Cl, COOR, CN, and so on in the molecule. Another advantage of $NaBH_4$ is that it can be used in water or alcoholic solvents and so reduces compounds, such as sugars that are not soluble in ethers.[915] Other solvents can be used with some modification of the borohydride. For example, butyltriphenylphosphonium borohydride reduces aldehydes to alcohols in dichloromethane.[916] A polymer-bound phase-transfer material with $NaBH_4$ in wet THF has also been used.[917] Sodium borohydride on alumina, under microwave irradiation, is also an effective reagent.[918] Sodium borohydride has been used on silica gel.[919] The scope of these reagents with ketones is similar to that with aldehydes. Lithium aluminum hydride reduces even sterically hindered ketones.

The double bonds that are generally not affected by metallic hydrides may be isolated or conjugated, but double bonds that are conjugated with the C=O group may or may not be reduced, depending on the substrate, reagent, and reaction conditions.[920] Some reagents that reduce only the C=O bonds of α,β-unsaturated aldehydes and ketones are AlH_3,[921] $NaBH_4$, or $LiAlH_4$ in the presence of lanthanide salts,[922] cobalt complexes,[923] nickel compounds,[924] I_2,[925] $NaBH_3(OAc)$,[926] $Zn(BH_4)_2$[927] on Y-zeolite,[928] and Et_3SiH.,[929] Also, both $LiAlH_4$[930] and $NaBH_4$[931] predominantly reduce only the C=O bonds of C=C–C=O systems in most cases, although substantial amounts of fully saturated alcohols have been found in some cases[930] (**15-14**). For some reagents that reduce only the C=C bonds of conjugated aldehydes and ketones, see **15-11**. A mixture of $InCl_3$ and $NaBH_4$ reduced both the C=C and C=O units of conjugated ketones.[932]

When a functional group is selectively attacked in the presence of a different functional group, the reaction is said to be *chemoselective*.[933] A number of reagents have been found to reduce aldehydes much faster than ketones. Among these[934] are sodium triacetoxyborohydride[935] ($NaBH_4$–HCOOH),[936] zinc borohydride in THF,[937] bis-(isopropoxytitanium borohydride),[938] a complex of $LialH_4$ and *N*-methyl-2-pyrrolidinone (of particular interest since it is stable in air and to heating),[939] and Raney nickel.[940] On

the other hand, ketones can be chemoselectively reduced in the presence of aldehydes with $NaBH_4$ in aq. EtOH at $-15°C$ in the presence of cerium trichloride $CeCl_3$.[941] The reagent lithium *n*-dihydropyridylaluminum hydride reduces diaryl ketones much better than dialkyl or alkyl aryl ketones.[942] Most other hydrides reduce diaryl ketones more slowly than other types of ketones. Saturated ketones can be reduced in the presence of α,β-unsaturated ketones with $NaBH_4$-50% MeOH—CH_2Cl_2 at $-78°C$[943] and with zinc borohydride.[944]

In general, $NaBH_4$ reduces carbonyl compounds in this order: aldehydes > α,β-unsaturated aldehydes > ketones > α,β-unsaturated ketones, and a carbonyl group of one type can be selectively reduced in the presence of a carbonyl group of a less reactive type.[945] A number of reagents will preferentially reduce the less sterically hindered of two carbonyl compounds, but by the use of DIBALH in the presence of the Lewis acid methylaluminum bis(2,16-di-*tert*-butyl-4-methylphenoxide), it was possible selectively to reduce the *more hindered* of a mixture of two ketones.[946] It is obvious that reagents can often be found to reduce one kind of carbonyl function in the presence of another.[947] For a discussion of selectivity in reduction reactions, see p. 1787. A syn-selective reduction of β-hydroxy ketones was achieved using $(i\text{PrO})_2TiBH_4$.[948]

Quinones are reduced to hydroquinones by $LiAlH_4$, $SnCl_2$—HCl, or sodium hydrosulfite ($Na_2S_2O_4$), as well as by other reducing agents.

The reagent lithium tri-*sec*-butylborohydride LiBH(*sec*-Bu)$_3$ (L-Selectride) reduces cyclic and bicyclic ketones in a highly stereoselective manner,.[949] For example, 2-methylcyclohexanone gave *cis*-2-methylcyclohexanol with an isomeric purity >99%. Both L-Selectride and the potassium salt (K-Selectride) reduce carbonyls in cyclic and acyclic molecules with high diastereoselectivity.[950] The more usual reagents, for example, $LiAlH_4$, $NaBH_4$, reduce relatively unhindered cyclic ketones either with little or no stereoselectivity[951] or give predominant formation of the more stable isomer (axial attack).[952] Mixed reagents, such as

$LiBH_3[N(C_3H_7)_2]$, gives high selectivity for axial attack.[953] Reduction of cyclohexanone derivatives with the very hindered $LiAlH(CEt_2CMe_3)_3$ gave primarily the cis-alcohol.[954] Cyclohexanones that have a large degree of steric hindrance near the carbonyl group usually give predominant formation of the less stable alcohol, even with $LiAlH_4$ and $NaBH_4$.

Other reagents reduce aldehydes and ketones to alcohols,[955] including:

1. *Hydrogen and a Catalyst.*[956] The most common catalysts are platinum and ruthenium, but homogeneous catalysts have also been used,[957] including copper on silica gel[958] and a ruthenium catalyst on mesoporous silica.[959] Before the discovery of the metal hydrides this was one of the most common ways of effecting this reduction, but it suffers from the fact that C=C, C≡C, C=N, and C≡N bonds are more susceptible to attack than C=O bonds.[960] For aromatic aldehydes and ketones, reduction to the hydrocarbon (**19-61**) is a side reaction, stemming from hydrogenolysis of the alcohol initially produced (**19-54**).
2. *Sodium in Ethanol.*[961] This is called the *Bouveault–Blanc procedure* and was more popular for the reduction of carboxylic esters (**19-38**) than of aldehydes or ketones before the discovery of $LiAlH_4$.

   For the reaction with sodium in ethanol the following mechanism[962] has been suggested:[963]

[953]Harrison, J.; Fuller, J.C.; Goralski, C.T.; Singaram, B. *Tetrahedron Lett.* ***1994***, *35*, 5201.

[954]Boireau, G.; Deberly, A.; Toneva, R. *Synlett* ***1993***, 585. In this study, reduction with LiAlH(O*t*-Bu)3 was shown to give primarily the trans-alcohol.

[955]This can also be done electrochemically. For a review, see Feoktistov, L.G.; Lund, H., in Baizer, M.M.; Lund, H. *Organic Electochemistry*, Marcel Dekker, NY, ***1983***, pp. 315–358, 315–326. See also, Coche, L.; Moutet, J. *J. Am. Chem. Soc.* ***1987***, *109*, 6887.

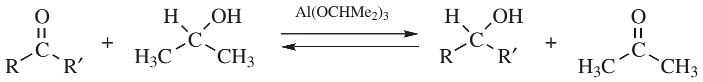
A ketyl

The ketyl intermediate can be isolated.[964]

3. *Isopropyl Alcohol and Aluminum Isopropoxide*. This is called the *Meerwein–Ponndorf–Verley reduction*.[965] It is reversible, and the reverse reaction is known as the *Oppenauer oxidation* (see **19-3**):



The equilibrium is shifted by removal of the acetone by distillation. There is a report of the reduction of benzaldehyde to benzyl alcohol by heating with Z-propanol at 225°C for 1 day.[966] The reaction takes place under very mild conditions and is highly specific for aldehydes and ketones, so that C=C bonds (including those conjugated with the C=O bonds) and many other functional groups can be present without themselves being reduced.[967] This includes acetals, so that one of two carbonyl groups in a molecule can be specifically reduced if the other is first converted to an acetal. β-Keto esters, β-diketones, and other ketones and aldehydes with a relatively high enol content do not give this reaction. A SmI_3-assisted version of this reduction has been reported.[968] Zeolites have been used as a medium for this reduction.[969] This reduction can be done catalytically[970] and an aluminum-free, zirconium zeolite catalyst has been developed.[971] A combination of Z-propanol with BINOL and $AlMe_3$ leads to reduction of α-chloroketones to the chlorohydrin with good enantioselectivity.[972] Microwave irradiation of a ketone with Z-propanol, KOH, and activated alumina gives good yields of the alcohol.[973]

[964]For example, see Rautenstrauch, V.; Geoffroy, M. *J. Am. Chem. Soc.* ***1976***, *98*, 5035; ***1977***, *99*, 6280.

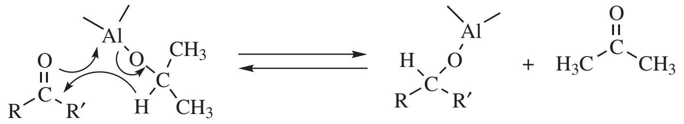
The Meerwein–Ponndorf–Verley reaction usually[974] involves a cyclic transition state:[975]



but in some cases 2 equivalents of aluminum alkoxide are involved: one attacking the carbon and the other the oxygen, a conclusion that stems from the finding that in these cases the reaction was 1.5 order in alkoxide.[976] Although, for simplicity, we have shown the alkoxide as a monomer, it actually exists as trimers and tetramers, and it is these that react.[977]

4. *Metal Reductions*. A single carbonyl group of an α-diketone can be reduced (to give an α-hydroxy ketone) by heating with zinc powder in aq. DMF[978] or zinc in methanol in the presence of benzyltriethylammonium chloride.[979] This has also been accomplished with aq. VCl_2[980] and with Zn—$ZnCl_2$—EtOH.[981] Aluminum and NaOH in aqueous methanol reduces ketones.[982] β-Hydroxy ketones are reduced with good anti-selectivity using an excess of SmI_2 in water,[983] and other ketones or aldehydes are reduced with SmI_2[984] in aq. THF,[985] in Z-propanol,[986] or methanol.[987] Other metals can be used, including $FeCl_3$/Zn in aq. DMF[988] or DME/MeOH.[989] 1,2-Diketones were reduced to the α-hydroxy ketone with TiI_4 in acetonitrile, followed by hydrolysis.[990] Ammonia and aq. $TiCl_3$ in methanol reduces ketones.[991]

[974]It has been that shown in some cases reduction with metal alkoxides, including aluminum isopropoxide, involves free-radical intermediates (SET mechanism): Screttas, C.G.; Cazianis, C.T. *Tetrahedron* ***1978***, *34*, 933; Nasipuri, D.; Gupta, M.D.; Banerjee, S. *Tetrahedron Lett.* ***1984***, *25*, 5551; Ashby, E.C.; Argyropoulos, J.N. *J. 5. *Boranes.* Borane (BH_3) and substituted boranes reduce aldehydes and ketones in a manner similar to their addition to C=C bonds (**15-16**).[992] That is, the boron adds to the oxygen and the hydrogen to the carbon:[993]

The borate is then hydrolyzed to the alcohol. Both 9-BBN[994] (p. 1077) and BH_3—Me_2S[995] reduce only the C=O group of conjugated aldehydes and ketones. A variety of alkylboranes can be used for reduction.[996] Borane reduction of a titanium complex of a 1,3-diketone gives the syn-diol.[997] Reduction occurs with $B_{10}H_{14}$ with $CeCl_3$,[998] Alane (AlH_3) derivatives can also be used, including diisobutylaluminum hydride.[999] Tributylborane in ionic solvents reduces aldehydes to alcohols.[1000]

6. *Tin Hydrides.* Tributyltin hydride reduces aldehydes to primary alcohols by simply heating in methanol.[1001] A mixture of Bu_3SnH and phenylboronic acid (p. 815) reduces aldehydes in dichloromethane.[1002] Reduction of ketones was achieved with Bu_2SnH_2 and a palladium catalyst.[1003] Using triaryltin hydrides with BF_3•OEt_2, where aryl is 2,6-diphenylbenzyl, selective reduction of aliphatic aldehydes in the presence of a conjugated aldehyde was achieved.[1004]

7. *Cannizzaro Reaction.* In the Cannizzaro reaction (**19-81**), aldehydes without an α hydrogen are reduced to alcohols.

8. *Silanes.* In the presence of bases, certain silanes can selectively reduce carbonyls. Epoxy-ketones are reduced to epoxy-alcohols, for example, with

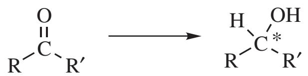
$(MeO)_3SiH$ and LiOMe.[1005] Controlling temperature and solvent leads to different ratios of syn- and anti- products.[1006] Silanes reduce ketones in the presence of $BF_3•OEt_2$[1007] and transition-metal compounds catalyze this reduction.[1008] Ketones are reduced with Cl_3SiH in the presence of pyrrolidine carboxaldehyde[1009] or under photochemical conditions.[1010] Polymethylhydrosiloxane with tetrabutylammonium fluoride reduces α-amino ketones to give the syn-amino alcohol.[1011]

9. *Ammonium Formates*. Sodium formate and trialkylammonium formates can be used to reduce aldehydes and ketones to the corresponding alcohol. Decanal was reduced to decanol, for example, using sodium formate in *N*-methyl-2-pyrrolidinone as a solvent.[1012] A mixture of formic acid and ethyl magnesium bromide was used to reduce decanal to decanol in 70% yield.[1013]

Unsymmetrical ketones are prochiral (p. 193); that is, reduction creates a new stereogenic center:



Much effort has been put into finding optically active reducing agents that will produce one enantiomer of the alcohol enantioselectively, and considerable success has been achieved,.[1014] Each reagent tends to show a specificity for certain types of ketones.[1015] H.C. Brown and co-workers[1016] reduced various types of ketone with a number of reducing agents. These workers also determined the relative effectiveness of various reagents for reduction of eight other types of ketone, including heterocyclic, aralkyl, β-keto esters, β-keto acids,[1017] and so on.[1016] In most cases, good enantioselectivity can be obtained with the proper reagent.[1018] Substituents that are

remote to the carbonyl group can play a role in facial selectivity of the reduction.[1019] Successful asymmetric reductions have been achieved with biologically derived reducing agents,[1020] such as baker's yeast,[1021] enzymes from other organisms,[1022] or with biocatalysts.[1023] Immobilized bakers yeast has been used in an ionic liquid.[1024]

Asymmetric reduction with very high enantioselectivity has also been achieved with achiral reducing agents and optically active catalysts.[1025] Two approaches are represented by (*1*) homogeneous catalytic hydrogenation with the catalyst 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl-ruthenium acetate, BINAP—Ru(OAc)$_2$,[1026] which reduces

dendritic chiral catalyst has been used in conjunction with borane,[1034] as well as other chiral additives can be used.[1035]

A third important method is the combination of $LiAlH_4$ or $NaBH_4$ with a chiral ligand, often in the presence of a transition-metal complex.[1036] Examples include $LiBH_4/NiCl_2$ and a chiral amino alcohol,[1037] $NaBH_4$ with chiral Lewis acid complexes,[1038] or $NaBH_4/Me_3SiCl$ and a chiral ligand.[1039] A mixture of $NaBH_4$ and Me_3SiCl with a catalytic amount of a chiral, polymer-bound sulfonamide leads to asymmetric reduction.[1040]

Enantioselective reduction is possible with the other methods mentioned above. Reduction with silanes and transition-metal catalysts, such as ruthenium compounds, is also very effective.[1041] This method gives high enantioselectivity with various types of ketone, especially α,β-unsaturated ketones. Chiral ruthenium catalysts have been used with triethylammonium formate for the enantioselective reduction.[1042] A ruthenium catalyst with a polymer-supported chiral ligand has been used with Bu_4NBr and HCO_2Na in water.[1043] Chiral additives mixed with surfactants have been used with sodium formate.[1044] Enantioselective reduction was observed with $PhSiH_3$ and copper compounds with a chiral ligand,[1045] with a mixture of ruthenium and silver catalysts,[1046] or with $Mn(dpm)_3$ and oxygen (dpm = diphenylmethylene).[1047] Asymmetric reduction was achieved using an

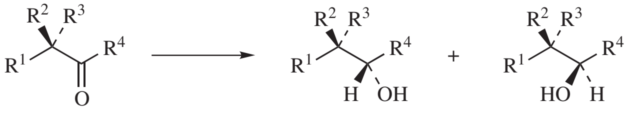
alkoxide or hydroxide base with a chiral rhodium,[1048] ruthenium,[1049] or iridium complex.[1050] A chiral samarium complex has been used in conjunction with Z-propanol.[1051] Chiral mercapto alcohols have also been used for asymmetric reduction.[1052]

Enantioselective reduction is not possible for aldehydes, since the products are primary alcohols in which the reduced carbon is not chiral, but deuterated aldehydes RCDO give a chiral product, and these have been reduced enantioselectively with B-(3-pinanyl)-9-borabicyclo[3.3.1]nonane (Alpine-Borane) with almost complete optical purity.[1053] Other chiral boranes can be used to reduce aldehydes or ketones.[1054]

In the above cases, an optically active reducing agent or catalyst interacts with a prochiral substrate. Asymmetric reduction of ketones has also been achieved with an achiral reducing agent, if the ketone is complexed to an optically active transition-metal Lewis acid.[1055]



There are other stereochemical aspects to the reduction of aldehydes and ketones. If there is a stereogenic center α to the carbonyl group,[1056] even an achiral reducing agent can give more of one diastereomer than of the other. Such

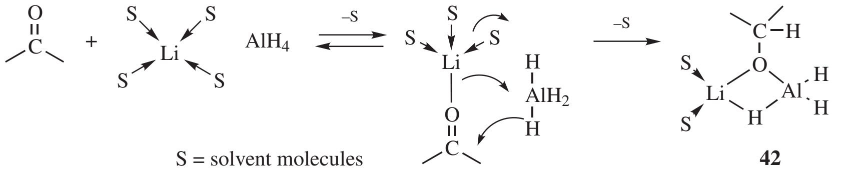
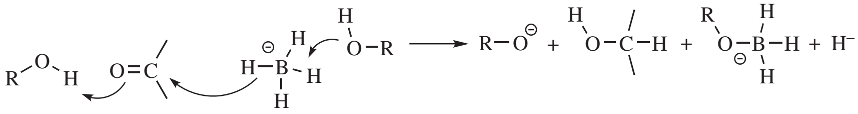
[1056]In theory, the chiral center can be anywhere in the molecule, but in practice, reasonable diastereoselectivity is most often achieved when it is in the α position. For examples of high diastereoselectivity when the chiral center is further away, especially in reduction of β-hydroxy ketones, see Narasaka, K.; Pai, F. *Tetrahedron* ***1984***, *40*, 2233; Hassine, B.B.; Gorsane, M.; Pecher, J.; Martin, R.H. *Bull. Soc.* ***1988***, *110*, 3560.

diastereoselective reductions have been carried out with considerable success.[1057] In most such cases Cram's rule (p. 168) is followed, but exceptions are known.[1058]

With most reagents there is an initial attack on the carbon of the carbonyl group by a hydride equivalent (H^-) although with BH_3[1059] the initial attack is on the oxygen. Detailed mechanisms are not known in most cases.[1060] With tetrahydroaluminate or borohydride compounds, the attacking species is the AlH_4^- (or BH_4^-) ion, which, in effect, transfers H^- to the carbon. The following mechanism has been proposed for $LiAlH_4$:[1061]



Evidence that the cation plays an essential role, at least in some cases, is that when the Li^+ was effectively removed from $LiAlH_4$ (by the addition of a crown ether), the reaction did not take place.[1062] The complex **42** must now be hydrolyzed to the alcohol. For $NaBH_4$, the Na^+ does not seem to participate in the transition state, but kinetic evidence shows that an OR group from the solvent does participate and remains attached to the boron:[1063]



Free H^- cannot be the attacking entity in most reductions with boron or aluminum hydrides because the reactions are frequently sensitive to the size of the MH_4^- [or MR_mH_n- or $M(OR)_mH_n^-$- etc.].

The question of whether the initial complex in the $LiAlH_4$ reduction (**42**, which can be written as $H{-}\overset{|}{\underset{|}{C}}{-}O\overset{\ominus}{A}lH_3$ = **43**) can reduce another carbonyl to give $H{-}\overset{|}{\underset{|}{C}}{-}O_2\overset{\ominus}{A}lH_4$ and so on has been controversial. It has been shown[1064] that this is probably not the case but that, more likely, **43** disproportionates to $(H{-}\overset{|}{\underset{|}{C}}{-}O)_4Al^{\ominus}$ and AlH_4^-, which is the only attacking species. Disproportionation has also been reported in the $NaBH_4$ reaction.[1065]

Aluminate, **43**, is essentially $LiAlH_4$ with one of the hydrogens replaced by an alkoxy group, that is, $LiAlH_3OR$. The fact that **43** and other alkoxy derivatives of $LiAlH_4$ are less reactive than $LiAlH_4$ itself has led to the use of such compounds as reducing agents that are less reactive and more selective than $LiAlH_4$.[1066] We have already met some of these, for example, $LiAlH(O{-}t{-}Bu)_3$ (reactions **19-39–19-41**; see also, Table 19.5). As an example of chemoselectivity in this reaction it may be mentioned that $LiAlH(O{-}t{-}Bu)_3$ has been used to reduce only the keto group in a molecule containing both keto and carboxylic ester groups.[1067] However, the use of such reagents is sometimes complicated by the disproportionation mentioned above, which may cause $LiAlH_4$ to be the active species, even if the reagent is an alkoxy derivative. Another highly selective reagent (reducing aldehydes and ketones, but not other functional groups), which does not disproportionate, is potassium triisopropoxyborohydride.[1068]

The mechanism of catalytic hydrogenation of aldehydes and ketones is probably similar to that of reaction **15-11**, although not much is known about it.[1069]

For other reduction reactions of aldehydes and ketones (see **19-61**, **19-76**, and **19-81**).

Carboxylic acids are easily reduced to primary alcohols by $LiAlH_4$.[1070] The reaction does not stop at the aldehyde stage (but see **19-40**). The conditions are particularly mild, the reduction proceeding quite well at room temperature. Other hydrides have also been used,[1071] but not $NaBH_4$ (see Table 19.5).[1072] Note, however, that complexion of the carboxylic acid with cyanuric chloride (2,4,6-trichlorotriazine) also smooth reduction to the alcohol.[1073] A combination of $NaBH_4$ and an arylboronic acid (p. 815) is also effective.[1074] Benzyltriethylammonium borohydride is dichloromethane also reduces carboxylic acids to the alcohol.[1075] Catalytic hydrogenation is also generally ineffective.[1076] Borane is particularly good for carboxyl groups (Table 19.4) and permits selective reduction of them in the presence of many other groups (although the reaction with double bonds takes place at about the same rate in ether solvents).[1077] Borane also reduces carboxylic acid salts.[1078] Aluminum hydride reduces COOH groups without affecting carbon–halogen bonds in the same molecule. The reduction has also been carried out with SmI_2 in basic media[1079] or aq. H_3PO_4,[1080] or simply with SmI_2 in water.[1081] A mixture of $NaBH_4$ and I_2 has been used to reduced amino acids to amino alcohols.[1082]

Lithium aluminum hydride reduces carboxylic esters to give 2 equivalents of alcohol.[1083] The reaction is of wide scope and has been used to reduce many esters. Where the interest is in obtaining R′OH, this is a method that is often a working equivalent of "hydrolyzing" esters. Lactones yield diols. Among the reagents that give the same products[1084] are DIBALH, lithium triethylborohydride, $LiAlH(Ot\text{-}Bu)_3$,[1085] and BH_3—SMe_2 in refluxing THF.[1086] Although $NaBH_4$ reduces phenolic esters, especially those containing electron-withdrawing groups,[1087] its reaction with other esters is usually so slow that it is not the reagent of choice (exceptions are known[1088]), and it is generally possible to reduce an aldehyde or ketone without reducing an ester function in the same molecule. Note that $NaBH_4$ in DMF—MeOH reduces aryl carboxylic esters to benzylic alcohols,[1089] and $NaBH_4$—LiCl with microwave irradiation also reduces esters to primary alcohols.[1090] However, $NaBH_4$ reduces esters in the presence of certain compounds (see Table 19.5).[1091] Carboxylic esters can also be reduced to alcohols by hydrogenation over copper chromite catalysts,[1092] although high pressures and temperatures are required. Ester functions generally survive low-pressure catalytic hydrogenations. Before the discovery of $LiAlH_4$, the most common way of carrying out the reaction was with sodium in ethanol, a method known as the *Bouveault–Blanc procedure*. This procedure is still sometimes used where selectivity is necessary (see also, **19-62**, **19-65**, and **19-59**).

Silanes, such as Ph_2SiH_2, with a catalytic amount of triphenylphosphine and a rhodium catalyst reduced esters to primary alcohols.[1093] Aliphatic silanes such as $EtMe_2SiH$, also reduced esters with a ruthenium catalyst.[1094]

19-39 Reduction of Acyl Halides

Hydro-de-halogenation or Dehalogenation

$$\text{RCOCl} \xrightarrow[-78^\circ\text{C}]{\text{LiAlH(O}t\text{-Bu)}_3} \text{RCHO}$$

Acyl halides can be reduced to aldehydes[1095] by treatment with lithium tri-*tert*-butoxyaluminum hydride in diglyme at −78°C.[1096] The R group may be alkyl or aryl and may contain many types of substituents, including NO_2, CN, and EtOOC groups. The reaction stops at the aldehyde stage because steric hindrance prevents further reduction under these conditions. Acyl halides can also be reduced to aldehydes by hydrogenolysis with palladium-on-barium sulfate as catalyst. This is called the *Rosenmund reduction*.[1097] A more convenient hydrogenolysis procedure involves palladium-on-charcoal as the catalyst, with ethyldiisopropylamine as acceptor of the liberated HCl and acetone as the solvent.[1098] The reduction of acyl halides to aldehydes has also been carried out[1099] with Bu_3SnH,[1100] with the $InCl_3$-catalyzed reaction with Bu_3SnH,[1101] with $NaBH_4$ in a mixture of DMF and THF,[1102] and with formic acid/NH_4OH.[1103] In some of these cases, the mechanisms are free-radical. There are several indirect methods for the conversion of acyl halides to aldehydes, most of them involving prior conversion of the halides to certain types of amides (see **19-41**). There is also a method in which the COOH group is replaced by a completely different CHO group (**16-87**).

19-40 Reduction of Carboxylic Acids, Esters, and Anhydrides to Aldehydes[1104]

Hydro-de-hydroxylation or Dehydroxylation (overall transformation)

$$RCOOH \longrightarrow RCHO$$
$$RCOOR' \longrightarrow RCHO$$

With most reducing agents, reduction of carboxylic acids generally gives the primary alcohol (**19-37**) and the isolation of aldehydes is not feasible. However, simple straight-chain carboxylic acids have been reduced to aldehydes[1105] by treatment with Li in $MeNH_2$ or NH_3 followed by hydrolysis of the resulting imine,[1106] with

$$RCOOH \xrightarrow[MeNH_2]{Li} RCH{=}N{-}Me \xrightarrow{H_2O} RCHO$$

with thexylchloro(or bromo)borane-Me_2S[1107] (see **15-16** for the thexyl group), $Me_2N{=}CHCl^+\ Cl^-$ in pyridine,[1108] and with diaminoaluminum hydrides.[1109] Benzoic acid derivatives were reduced to benzaldehyde derivatives with NaH_2PO_2 and a diacylperoxide and a palladium catalyst.[1110] Caproic and isovaleric acids have been reduced to aldehydes in 50% yields or better with DIBALH (i-Bu_2AlH) at -75 to $-70°C$.[1111] Carboxylic acids can be reduced directly on Claycop–H_2O_2 using microwave irradiation.[1112]

Carboxylic esters have been reduced to aldehydes with DIBALH at $-70°C$, with diaminoaluminum hydrides,[1113] with $LiAlH_4$–Et_2NH,[1114] and for phenolic esters with $LiAlH(O{-}t\text{-}Bu)_3$ at 0°C.[1115] Aldehydes have also been prepared by reducing ethyl thiol esters (RCOSEt) with Et_3SiH and a Pd—C catalyst.[1116] Pretreatment of

the acid with Me_3SiCl followed by reduction with DIBALH also gives the aldehyde.[1117] Thioesters have been reduced to the aldehyde with lithium metal in THF at −78°C, followed by quenching with methanol.[1118]

Anhydrides, both aliphatic and aromatic, as well as mixed anhydrides of carboxylic and carbonic acids, have been reduced to aldehydes in moderate yields with disodium tetracarbonylferrate, $Na_2Fe(CO)_4$.[1119] Heating a carboxylic acid, presumably to form the anhydride, and then reaction with Na/EtOH leads to the aldehyde.[1120]

Acid chlorides are reduced to aldehydes with Bu_3SnH and a nickel catalyst.[1121]

Also see, **19-62** and **19-38**.

OS **VI**, 312; **VIII**, 241, 498.

19-41 Reduction of Amides to Aldehydes

Hydro-de-dialkylamino-substitution

$$RCONR_2' + LiAlH_4 \longrightarrow RCHO + NHR_2'$$

N,N-Disubstituted amides can be reduced to amines with $LiAlH_4$ (see **19-64**), but also to aldehydes.[1122] Keeping the amide in excess gives the aldehyde rather than the amine. Sometimes it is not possible to prevent further reduction and primary alcohols are obtained instead. Other reagents[1123] that give good yields of aldehydes are DIBALH,[1124] $LiAlH(O{-}t\text{-}Bu)_3$, diaminoaluminum hydrides,[1125] disiamylborane (see **15-16** for the disiamyl group), [1126] and $Cp_2Zr(H)Cl$.[1127]

Aldehydes have been prepared from carboxylic acids or acyl halides by first converting them to certain types of amides that are easily reducible. There are several examples:[1128]

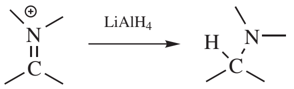
with other reducing agents.[1136] A mixture of Sm/I_2[1137] or In/NH_4Cl[1138] reduces imines. Reduction with Bu_2SnClH in HMPA has been shown to be chemoselective for imines.[1139] Iminium salts are also reduced by $LiAlH_4$, although here there is no "addition" to the nitrogen:[1140] Silanes[1141] with a triarylborane catalyst reduces *N*-sulfonyl imines[1142] as does TiI_4.[1143] Imines are reduced with Cl_3SiH and pyrrolidine carboxaldehyde,[1144] Samarium bromide in HMPA,[1145] Z-propanol with a ruthenium catalyst,[1146] and with triethylammonium formate with microwave irradiation.[1147] Oximes are reduced with hydrogen gas an a catalytic amount of 48% HBr.[1148]



Oximes are generally reduced to amines (**19-48**),[1149] but simple reduction to give hydroxylamines can be accomplished with borane[1150] or sodium cyanoborohydride.[1151] Oxime *O*-ethers are reduced with Bu_3SnH and BF_3•OEt_2.[1152] Diazo compounds (ArN=NAr) are reductively cleaved to aniline derivatives with Zn and ammonium formate in methanol.[1153]

Reduction of imines has been carried out enantioselectively.[1154] Catalytic hydrogenation with a chiral iridium[1155] or palladium[1156] catalyst has been used. Catalytic hydrogenation of iminium salts with a chiral ruthenium catalyst gives the amine.[1157] In a related reaction, enamines were reduced by hydrogenation over a chiral rhodium catalyst.[1158] An ammonium formate with a chiral ruthenium complex was used with imines.[1159] Hydrogenation of oximes with Pd/C and a nickel complex gives the imine, and in the presence of a lipase and ethyl acetate the final product was an acetamide, formed with high enantioselectivity.[1160] Conjugated *N*-sulfonyl imines are reduced to the conjugated sulfonamide with good enantioselectivity using a chiral rhodium catalyst in the presence of LiF and $PhSnMe_3$.[1161] Phosphinyl imines, $R_2C{=}N{-}P({=}O)Ar_2$, are reduced with high enantioselectivity using a chiral copper catalyst.[1162] Silanes, such as $PhSiH_3$, can be used for the reduction of imines, and in the presence of a chiral titanium catalyst the resulting amine was formed with excellent enantioselectivity.[1163]

Isocyanates have been catalytically hydrogenated to *N*-substituted formamides: RNCO → R–NH–CHO.[1164] Isothiocyanates were reduced to thioformamides with SmI_2 in HMPA/*t*-BuOH.[1165]

[1167]See Brown, H.C.; Choi, Y.M.; Narasimhan, S. *Synthesis* ***1981***, 605.

reduce nitriles except in alcoholic solvents with a catlayst, such as $CoCl_2$,[1168] $NiCl_2$,[1169] or Raney nickel.[1170] A mixture of $NaBH_4/NiCl_2$ in acetic anhydride reduces the nitrile to the amine, which is trapped as the acetamide.[1171] Lithium dimethylamino- borohydride ($LiBH_3NMe_2$) reduces aryl nitriles to the corresponding benzylamines.[1172]

The reduction of nitriles is of wide scope and has been applied to many nitriles. When catalytic hydrogenation is used, secondary amines, $(RCH_2)_2NH$, are often side products.[1173] These can be avoided by adding a compound, such as acetic anhydride, which removes the primary amine as soon as it is formed,[1174] or by the use of excess ammonia to drive the equilibria backward.[1175] Sponge nickel[1176] or nickel on silica gel[1177] have been used for the catalytic hydrogenation of aryl nitriles to amines.

Attempts to stop with the addition with only 1 equivalent of hydrogen, have failed that is, to convert the nitrile to an imine, except where the imine is subsequently hydrolyzed (**19-44**).

N-Alkylnitrilium ions are reduced to secondary amines by $NaBH_4$.[1178]

$$RCN \xrightarrow{R'_3O^+BF_4^-} R{-}C{\equiv}N^{\oplus}{-}R' \xrightarrow[\text{diglyme}]{NaBH_4} RCH_2{-}NH{-}R'$$

Since nitrilium salts can be prepared by treatment of nitriles with trialkyloxonium salts (see **16-8**), this is a method for the conversion of nitriles to secondary amines.

Note that the related compounds, the isonitriles ($R{-}^{\oplus}N{\equiv}C^{\ominus}$, also called isocyanides) have been reduced to *N*-methylamines with $LiAlH_4$, as well as with other reducing agents.

19-44 The Reduction of Nitriles to Aldehydes

Hydro,oxy-de-nitrilo-tersubstitution

$$R{-}C{\equiv}N \xrightarrow[\text{2. hydrolysis}]{\text{1. HCl, SnCl}_2} RCH{=}O$$

There are two principal methods for the reduction of nitriles to aldehydes.[1179] In one of these, known as the *Stephen reduction*, the nitrile is treated with HCl to form an iminium salt, **47**.

$$RCCl = \overset{\oplus}{N}H_2 \quad \overset{\ominus}{Cl}$$

47

Iminium salt **47** is reduced with anhydrous $SnCl_2$ to RCH=NH, which precipitates as a complex with $SnCl_4$ and is then hydrolyzed (**16-2**) to the aldehyde. The Stephen reduction is most successful when R is aromatic, but it can be done for aliphatic R up to about six carbons.[1180] It is also possible to prepare **47** in a different way, by treating ArCONHPh with PCl_5, which can then be converted to the aldehyde. This is known as the *Sonn–Müller method*. Aqueous formic acid in the presence of PtO_2, followed by treatment with aqueous acid, converts aryl nitriles to aryl aldehydes.[1181]

The other way of reducing nitriles to aldehydes involves using a metal hydride reducing agent to add 1 equivalent of hydrogen and hydrolysis, *in situ*, of the resulting imine (which is undoubtedly coordinated to the metal). This has been carried out with $LiAlH_4$, $LiAlH(OEt)_3$,[1182] $LiAlH(NR_2)_3$,[1183] and DIBALH.[1184] The metal hydride method is useful for aliphatic and aromatic nitriles.

OS **III**, 626, 818; **VI**, 631.

19-45 Reduction of Nitro Compounds to Amines

$$RNO_2 \xrightarrow[\text{HCl}]{\text{Zn}} RNH_2$$

Both aliphatic[1185] and aromatic nitro compounds can be reduced to amines, although the reaction has been applied much more often to aromatic nitro

compounds, owing to their greater availability. Many reducing agents have been used to reduce aromatic nitro compounds, the most common being Zn, Sn, or Fe (or sometimes other metals) and acid, and catalytic hydrogenation.[1186] Indium metal in aqueous ethanol with ammonium chloride[1187] or with water in aq. THF[1188] also reduces aromatic nitro compounds to the corresponding aniline derivative. Indium metal in methanol, with acetic anhydride and acetic acid, converts aromatic nitro compounds to the acetanilide.[1189] Samarium and a catalytic amount of iodine also accomplishes this reduction,[1190] as does Sm with a bipyridinium dibromide in methanol.[1191] Samarium metal in methanol with ultrasound also reduces aryl nitro compounds.[1192] Sodium sulfide (NaHS) on alumina with microwave irradiation reduces aryl nitro compounds to aniline derivatives.[1193] A mild reduction uses Al(Hg) in aq. THF with ultrasound.[1194] An Al/$NiCl_2$ reagent was used to reduced the nitro group of a polymer-bound $CH_2OCH_2C_6H_4NO_2$ moiety.[1195] Some other reagents used[1196] were $Et_3SiH/RhCl(PPh_3)_3$,[1197] AlH_3—$AlCl_3$, Mn with $CrCl_2$,[1198] nanoparticulate iron in water at 210°C,[1199] formic acid and Pd—C[1200] for formic acid with Raney nickel in methanol,[1201] and sulfides, such as NaHS, $(NH_4)_2S$, or polysulfides. The reaction with sulfides or polysulfides is called the *Zinin reduction*.[1202] Amines are also the products when nitro compounds, both alkyl and aryl, are reduced with $HCOONH_4$—Pd—C.[1203] Many other functional groups (e.g., COOH, COOR, CN, amide) are not affected by this reagent (although ketones are reduced, see **19-33**). With optically active alkyl substrates this method gives

retention of configuration.[1204] Ammonium formate in methanol reduces aromatic nitro compounds.[1205] Lithium aluminum hydride reduces aliphatic nitro compounds to amines, but with aromatic nitro compounds the products with this reagent are azo compounds (**19-80**). Most metal hydrides, including $NaBH_4$ and BH_3, do not reduce nitro groups at all, although both aliphatic and aromatic nitro compounds have been reduced to amines with $NaBH_4$ and various catalysts, such as $NiCl_2$ or $CoCl_2$[1206] phthalocyanine iron (II),[1207] and $ZrCl_4$.[1208] Borohydride exchange resin in the presence of $Ni(OAc)_2$, however, gives the amine.[1209] Treatment of aromatic nitro compounds with $NaBH_4$ alone has resulted in reduction of the *ring* to a cyclohexane ring with the nitro group still intact[1210] or in cleavage of the nitro group from the ring.[1211] With $(NH_4)_2S$ or other sulfides or polysulfides it is often possible to reduce just one of two or three nitro groups on an aromatic ring or on two different rings in one molecule.[1212] The nitro groups of *N*-nitro compounds can also be reduced to amino groups, for example, nitrourea $NH_2CONHNO_2$ gives semicarbazide $NH_2CONHNH_2$. Bakers yeast reduces aromatic nitro compounds to aniline derivatives.[1213] A combination of $NaH_2PO_2/FeSO_4$ with microwave irradiation reduces aromatic nitro compounds to aniline derivatives.[1214] Hydrazine on alumina, with $FeCl_3$ and microwave irradiation accomplishes this reduction.[1215] Hydrazine–formic acid with Raney nickel in methanol reduces aromatic nitro compounds.[1216] Heating aromatic nitro compounds with 57% HI reduces the nitro group to the amino group.[1217]

With some reducing agents, especially with aromatic nitro compounds, the reduction can be stopped at an intermediate stage, and hydroxylamines (**19-46**), hydrazobenzenes, azobenzenes (**19-80**), and azoxybenzenes (**19-79**) can be obtained in this manner. However, nitroso compounds, which are often postulated as intermediates, are too reactive to be isolated, if indeed they are intermediates. Reduction by metals in mineral acids cannot be stopped, but always produces the amine.

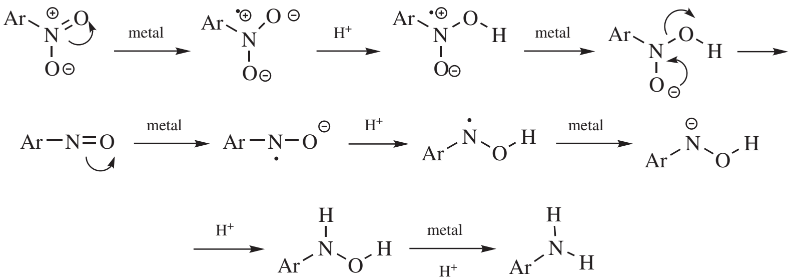
The mechanisms of these reductions have not been studied much, although it is usually presumed that, at least with some reducing agents, nitroso compounds and hydroxylamines are intermediates. Both of these types of compounds give amines when exposed to most of these reducing agents (**19-47**), and hydroxylamines can be isolated (**19-46**). With metals and acid the following path has been suggested:[1218]



Certain aromatic nitroso compounds (Ar—NO) can be obtained in good yields by irradiation of the corresponding nitro compounds in 0.1 *M* aq. KCN with uv light.[1219] The reaction has also been performed electrochemically.[1220] When nitro compounds are treated with most reducing agents, nitroso compounds are either not formed or react further under the reaction conditions and cannot be isolated.

Reductive alkylation of aromatic nitro compounds is possible. The reaction of nitrobenzene with allylic or benzyl halides in the presence of an excess of tin metal in methanol, leads to the *N,N*-diallyl or dibenzyl aniline.[1221] A similar reaction occurs with nitrobenzene, allyl bromide, and indium metal in aq. acetonitrile.[1222]

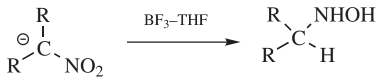
purpose have been SmI_2,[1224] N_2H_4—Rh—C,[1225] and $KBH_4/BiCl_3$.[1226] Borane in THF reduces aliphatic nitro enolate anions to hydroxylamines:[1227]



Nitro compounds have been reduced electrochemically, to hydroxylamines, as well as to other products.[1228]

OS **I**, 445; **III**, 668; **IV**, 148; **VI**, 803; **VIII**, 16.

19-47 Reduction of Nitroso Compounds and Hydroxylamines to Amines

N-Dihydro-de-oxo-bisubstitution

$$\mathrm{RNO} \xrightarrow[\mathrm{HCl}]{\mathrm{Zn}} \mathrm{RNH_2}$$

N-Hydro-de-hydroxylation or *N*-Dehydroxylation

$$\mathrm{RNHOH} \xrightarrow[\mathrm{HCl}]{\mathrm{Zn}} \mathrm{RNH_2}$$

Nitroso compounds and hydroxylamines can be reduced to amines by the same reagents that reduce nitro compounds (**19-45**). Reaction with CuCl, and then phenylboronic acid (p. 815), also reduces nitroso compounds to the amine.[1229] A hydroxylamine can be reduced to the amine with CS_2 in acetonitrile.[1230] Indium metal in EtOH/aq. NH_4Cl reduces hydroxylamines to the amine.[1231] *N*-Nitroso compounds are similarly reduced to hydrazinesm $R_2N—NO \rightarrow R_2N–NH_2$.[1232]

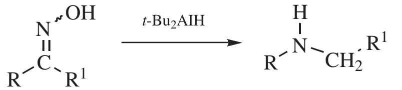
[1231]Cicchi, S.; Bonanni, M.; Cardona, F.; Revuelta, J.; Goti, A. *Org. Lett.* ***2003***, *5*, 1773.

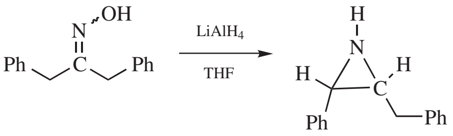
[1232]For examples of this reduction, accomplished with titanium reagents, see Entwistle, I.D.; Johnstone, R.A.W.; Wilby, A.H. *Tetrahedron* ***1982***, *38*, 419; Lunn, G.; Sansone, E.B.; Keefer, L.K. *J. Org. Chem.* ***1984***, *49*, 3470.

Both aldoximes and ketoximes can be reduced to primary amines with $LiAlH_4$. The reaction is slower than with ketones, so that, for example, PhCOCH=NOH gave 34% PhCHOHCH=NOH.[1233] Among other reducing agents that give this reduction[1234] are zinc and acetic acid, BH_3,[1235] $NaBH_3CN$—$TiCl_3$,[1236] polymethylhydrosiloxane (PMHS) with Pd-C,[1237] and sodium and an alcohol.[1238] Catalytic hydrogenation is also effective.[1239] The reduction has been performed enantioselectively with Baker's yeast[1240] and with Ph_2SiH_2 and an optically active rhodium complex catalyst.[1241] Reduction of oximes with indium metal in acetic anhydride/acetic acid–THF leads to the acetamide.[1242] Oxime *O*-ethers are reduced to the amine with modest enantioselectivity using a chiral oxazaboroline.[1243]

When the reducing agent is DIBALH, the product is a secondary amine, arising from a rearrangement:[1244]



With certain oximes (e.g., those of the type $ArCH_2CR$=NOH), treatment with $LiAlH_4$ gives aziridines,[1245] for example,



Hydrazones, arylhydrazones, and semicarbazones can also be reduced to amines with various reducing agents, including Zn—HCl and H_2 and Raney nickel.

Oximes have been reduced in a different way, to give imines ($RR'C{=}NOH \rightarrow RR'C{=}NH$), which are generally unstable but which can be trapped to give useful products. Among reagents used for this purpose have been $Bu_3P{-}SPh_2$[1246] and $Ru_3(CO)_{12}$.[1247] Oximes can also be reduced to hydroxylamines (**19-42**). Nitrones have been reduced to imines using $AlCl_3{\bullet}6\ H_2O/KI$ followed by $Na_2S_2O_3{-}H_2O$.[1248]

OS **II**, 318; **III**, 513; **V**, 32, 83, 373, 376.

19-49 Reduction of Aliphatic Nitro Compounds to Oximes or Nitriles

$$RCH_2NO_2 \xrightarrow[\text{HOAc}]{\text{Zn}} RCH{=}NOH$$

Nitro compounds that contain an α hydrogen can be reduced to oximes with zinc dust in acetic acid[1249] or with other reagents, among them $CS_2{-}NEt_3$,[1250] $CrCl_2$,[1251] and (for α-nitro sulfones) $NaNO_2$.[1252] α-Nitro alkenes have been converted to oximes

with sodium hypophosphite, indium with aq. $NH_4Cl/MeOH$,[1253] and with Pb—HOAc—DMF, as well as with certain other reagents.[1254]

$$RCH_2NO_2 \xrightarrow{NaBH_2S_3} RC{\equiv}N$$

Primary aliphatic nitro compounds can be reduced to aliphatic nitriles with sodium dihydro(trithio)borate[1087] or with *t*-BuN≡C/BuN=C=O.[1255] Secondary compounds give mostly ketones (e.g., nitrocyclohexane gave 45% cyclohexanone, 30% cyclohexanone oxime, and 19% *N*-cyclohexylhydroxylamine). Tertiary aliphatic nitro compounds do not react with this reagent (see also, **19-45**).

19-50 Reduction of Azides to Primary Amines

N-Dihydro-de-diazo-bisubstitution

$$RN_3 \xrightarrow{LiAlH_4} RNH_2$$

Azides are easily reduced to primary amines by $LiAlH_4$, as well as by a number of other reducing agents,[1256] including $NaBH_4$, $NaBH_4/LiCl$,[1257] $NaBH_4/CoCl_2/H_2O$,[1258] $NaBH_4/ZrCl_4$,[1259] $BHCl_2$•SMe_2,[1260] H_2 and a catalyst, $Bu_3SnH/PhSiH_3$/AIBN,[1261] Mg or Ca in MeOH,[1262] $Sm/NiCl_2$,[1263] $Zn\text{-}FeCl_3$/EtOH,[1264] Zn/NH_4Cl/aq. EtOH,[1265] $FeCl_3$/NaI,[1266] $FeSO_4/NH_3$/MeOH,[1267] baker's yeast,[1268] Sm/I_2,[1269] Indium metal in EtOH,[1270] $LiMe_2NBH_3$,[1271] and tin complexes prepared from $SnCl_2$ or $Sn(SR)_2$.[1272] Reaction with PPh_3 leads to a phosphazide, $Ph_3P{=}N{-}N{=}N{-}R$, which loses nitrogen in what is called the *Staudinger reaction*[1273] a method to prepare phosphazo compounds, but in this case leads to reduction. Alkylation is possible, and the reaction of an alkyl azide with PMe_3, and then an excess of iodomethane leads to the *N*-methylated amine.[1274] This reaction, combined with RX → RN_3 (**10-43**), is an important way of converting alkyl halides RX to primary amines RNH_2; in some cases the two procedures have been combined into one laboratory step.[1275] Sulfonyl azides RSO_2N_3

have been reduced to sulfonamides RSO_2NH_2 by irradiation in isopropyl alcohol[1276] and with NaH.[1277]

OS **V**, 586; **VII**, 433.

19-51 Reduction of Miscellaneous Nitrogen Compounds

Isocyanate–methylamine transformation $R{-}N{=}C{=}O \xrightarrow{LiAlH_4} R{-}NH{-}CH_3$

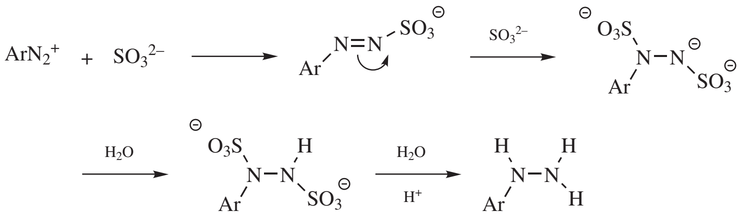
Isothiocyanate–methylamine transformation $R{-}N{=}C{=}S \xrightarrow{LiAlH_4} R{-}NH{-}CH_3$

***N,N*-Dihydro-addition** $Ar{-}N{=}N{-}Ar \xrightarrow[\text{catalyst}]{H_2} Ar{-}NH{-}NH{-}Ar$

Diazonium–arylhydrazone reduction $ArN_2^+\ Cl^- \xrightarrow{Na_2SO_3} ArNHNH_2$

***N*-Hydro-de-nitroso-substitution** $R_2N{-}NO \xrightarrow[Ni]{H_2} R_2NH$

Isocyanates and isothiocyanates are reduced to methylamines on treatment with $LiAlH_4$. $LiAlH_4$ does not usually reduce azo compounds[1278] (indeed these are the products from $LiAlH_4$ reduction of nitro compounds, **19-80**), but these can be reduced to hydrazo compounds by catalytic hydrogenation or with diimide[1279] (see **15-11**). Diazonium salts are reduced to hydrazines by sodium sulfite. This reaction probably has a nucleophilic mechanism.[1280]



The initial product is a salt of hydrazinesulfonic acid, which is converted to the hydrazine by acid treatment. Diazonium salts can also be reduced to arenes (**19-69**). *N*-Nitrosoamines can be denitrosated to secondary amines by a number of reducing agents, including H_2 and a catalyst,[1281] BF_3—THF—$NaHCO_3$,[1282] and $NaBH_4$—$TiCl_4$,[1283] as well as by hydrolysis.[1284]

A cyano group can be reduced to a methyl group by treatment with a terpene, such as limonene (which acts as reducing agent) in the presence of palladium–charcoal.[1285] Hydrogen gas (H_2) is also effective,[1286] although higher temperatures are required. The group R may be alkyl or aryl. Cyano groups CN have also been reduced to CH_2OH, in the vapor phase, with 2-propanol and zirconium oxide.[1287]

Aryl nitro compounds are reduced to diaryl hydrazines with Al—KOH in methanol.[1288]

OS **I**, 442; **III**, 475. Also see, OS **V**, 43.

C. Reactions in Which a Heteroatom Is Removed from the Substrate

19-52 Reduction of Silanes to Methylene Compounds

***Si*-Hydrogen-uncoupling**

$$R\text{–}SiR'_3 \longrightarrow R\text{–}H$$

In certain cases, the C—Si bond of silanes can be converted to C—H. α-Silyl esters are reduced to esters with mercuric acetate and tetrabutylammonium fluoride, for example.[1289]

19-53 Reduction of Alkyl Halides

Hydro-de-halogenation or Dehalogenation

$$RX \longrightarrow RH$$

This type of reduction can be accomplished with many reducing agents.[1290] A powerful, but highly useful reagent is $LiAlH_4$,[1291] which reduces almost all types of

alkyl halide, including vinylic, bridgehead, and cyclopropyl halides.[1292] Reduction with lithium aluminum deuteride serves to introduce deuterium into organic compounds. An even more powerful reducing agent, is lithium triethylborohydride ($LiEt_3BH$), which rapidly reduces primary, secondary, allylic, benzylic, and neopentyl halides, but not tertiary (these give elimination) or aryl halides.[1293] Another powerful reagent, which reduces primary, secondary, tertiary, allylic, vinylic, aryl, and neopentyl halides, is a complex formed from lithium trimethoxyaluminum hydride, $LiAlH(OMe)_3$, and CuI.[1294] A milder reducing agent is $NaBH_4$ in a dipolar aprotic solvent, such as Me_2SO, DMF, or sulfolane,[1295] which at room temperature or above reduces primary, secondary, and some tertiary[1296] halides in good yield without affecting other functional groups that would be reduced by $LiAlH_4$, for example, COOH, COOR, CN.[1297] A mixture of $NaBH_4$ and $InCl_3$ efficiently reduces secondary bromides.[1298] Borohydride exchange resin is also an effective reducing agent in the presence of metal catalysts, such as $Ni(OAc)_2$,[1299] and Bu_4NBH_4, is also effective.[1300]

Other reducing agents[1301] include zinc (with acid or base), $SnCl_2$, SmI_2—THF—HMPA,[1302] and Et_3SiH in the presence of $AlCl_3$.[1303] Diethyl phosphonate–Et_3N,[1304] phosphorus tris(dimethylamide) $(Me_2N)_3P$,[1305] and organotin hydrides R_nSnH_{4-n}[1306] (chiefly Bu_3SnH) usually used in conjunction with a radical

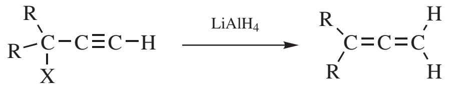
initiator, such as AIBN.[1307] Tributyltin hydride can be used in conjunction with transition-metal salts, such as $InCl_3$.[1308] The organotin hydride ($MeOCH_2$-$CH_2OCH_2CH_2CH_2)_3SnH$ reduces alkyl halides and is water soluble, unlike Bu_3SnH.[1309] In a related area, silylated cyclohexadienes have been used with AIBN as radical-chain reducing reagents, effective for tertiary halides.[1310] Other transition metal-based reducing agents include $NiCl_2$,[1311] $Ni(OAc)_2/Al(acac)_3$/NaH.[1312] Raney nickel in Z-propanol reduces primary iodides in the presence of a lactone moiety.[1313] Aluminum amalgam efficiently reduced an iodohydrin to the alcohol.[1314] A polymer-bound dialkyltin halide has been used in conjunction with $NaBH_4$ to reduce alkyl bromides.[1315]

Reduction, especially of bromides and iodides, can also be effected by catalytic hydrogenation,[1316] and electrochemically.[1317] Raney nickel by itself can reduce alkyl halides.[1318] A good reducing agent for the removal of all halogen atoms in a polyhalo compound (including vinylic, allylic, geminal, and even bridgehead halogens) is lithium[1319] or sodium[1320] and *t*-BuOH in THF. Propargylic halides can often be reduced with allylic rearrangement to give allenes.[1321]



The choice of a reducing agent usually depends on what other functional groups are present. Each reducing agent reduces certain groups and not others. This type of

selectivity is called *chemoselectivity*. A chemoselective reagent is one that reacts with one functional group (e.g., halide), but not another (e.g., C=O). For example, there are several reagents that reduce only the halogen of α-halo ketones, leaving the carbonyl group intact.[1322] Among them are polymer-supported triphenylphosphine,[1323] decaborane with 10% Pd/C,[1324] Bi in aq. THF[1325] or In metal in water,[1326] and *i*-Bu_2AlH—$SnCl_2$.[1327] In a similar chemoselective reaction, the halogen in α-haloimines has been reduced with $SnCl_2$/MeOH without reducing the C=N bond.[1328]

Both $NaBH_3CN$—$SnCl_2$.[1329] and the *n*-butyllithium ate complex of B-*n*-butyl-9-BBN[1330] (see p. 1077) reduce tertiary alkyl, benzylic, and allylic halides, but do not react with primary or secondary alkyl or aryl halides. Another highly selective reagent, in this case for primary and secondary iodo and bromo groups, is sodium cyanoborohydride, $NaBH_3CN$, in HMPA.[1331] Most of the reducing agents mentioned reduce chlorides, bromides, and iodides, but organotin hydrides also reduce fluorides.[1332] See p. 1787 for a discussion of selectivity in reduction reactions.

Vinyl halides can be reduced to the corresponding alkene is some cases.[1333] As mentioned above, electrochemical reduction of aryl and vinyl halides is well known.[1334] When vinyl dibromides, such as $RCH{=}CBr_2$, are treated with $(MeO)_2P({=}O)H$ and triethylamine, for example, the product is the vinyl bromide RCH=HBr.[1335] Indium in ethanol accomplishes the same transformation.[1336] Similar reduction occurs when vinyl diiodides are treated with Zn–Cu in acetic acid.[1337]

With $LiAlH_4$ and most other metallic hydrides, the mechanism usually consists of simple nucleophilic substitution with attack by hydride ion that may or may not be completely free. The mechanism is S_N2 rather than S_N1, since primary halides react better than secondary or tertiary (tertiary generally give alkenes or do not react at all) and since Walden inversion has been demonstrated. However, rearrangements found in the reduction of bicyclic tosylates with $LiAlH_4$ indicate that the S_N1 mechanism can take place.[1338] There is evidence that $LiAlH_4$ and other metal hydrides can also reduce halides by an SET mechanism,[1339] especially those, such as vinylic,[1340] cyclopropyl,[1341] or bridgehead halides, that are resistant to nucleophilic substitution. Reduction of halides by $NaBH_4$ in 80% aqueous diglyme[1342] and by BH_3 in nitromethane[1343] takes place by an S_N1 mechanism. It is known that $NaBH_4$ in sulfolane reduces tertiary halides possessing a β-hydrogen by an elimination-addition mechanism.[1344]

The mechanism for reduction of alkyl halides is not always nucleophilic substitution. For example, reductions with organotin hydrides generally[1345] take place by free-radical mechanisms,[1346] as do those with $Fe(CO)_5$. Alkyl halides, including fluorides and polyhalides, can be reduced with magnesium and a secondary or tertiary alcohol (most often 2-propanol).[1347] This is actually an example of the occurrence in one step of the sequence:

$$RX \longrightarrow RMgX \longrightarrow H^+RH$$

More often the process is carried out in two separate steps (**12-36** and **12-22**).

19-54 Reduction of Alcohols[1348]

Hydro-de-hydroxylation or Dehydroxylation

$$ROH + H_2 \xrightarrow{\text{catalyst}} RH$$

The hydroxyl groups of most alcohols can seldom be cleaved by catalytic hydrogenation and alcohols are often used as solvents for hydrogenation of other compounds. However, benzyl-type alcohols undergo the reaction readily and have often been reduced.[1349] Diaryl and triarylcarbinols are similarly easy to reduce and this has been accomplished with $LiAlH_4$—$AlCl_3$,[1350] with $NaBH_4$ in F_3CCOOH,[1351] and with iodine, water, and red phosphorus (OS **I**, 224). Other reagents have been used,[1352] among them PPh_3/diethyl-azo-dicarboxylate and arylsulfonyl hydrazine,[1353] PPh_3 and electrolysis,[1354] Me_3SiCl—MeI—MeCN,[1355] Me_3SiCl—NaI,[1356] Et_3SiH—BF_3,[1357] SmI_2—THF—HMPA,[1358] and tin and HCl. The reduction of secondary alcohols was accomplished using Ph_2SiClH and $InCl_3$.[1359] 1,3-Diols are especially susceptible to hydrogenolysis. Tertiary alcohols can be reduced by catalytic hydrogenolysis when the catalyst is Raney nickel.[1360] Allylic alcohols (and ethers and acetates) can be reduced (often with accompanying allylic rearrangement) with Zn amalgam and HCl, as well as with certain other reagents.[1361] α-Acetylenic alcohols are converted to alkynes by reduction of their cobalt carbonyl complexes with $NaBH_4$ and CF_3COOH.[1362] Reagents that reduce the OH group

of α-hydroxy ketones without affecting the C=O group include lithium diphenylphosphide, Ph_2PLi,[1363] red phosphorus–iodine,[1364] and Me_3SiI.[1365]

Alcohols can also be reduced indirectly by conversion to a sulfonate and reduction of that compound (**19-57**). The two reactions can be carried out without isolation of the sulfonate if the alcohol is treated with pyridine–SO_3 in THF, and $LiAlH_4$ then added.[1366] Another indirect reduction that can be done in one step involves treatment of the alcohol (primary, secondary, or benzylic) with NaI, Zn, and Me_3SiCl.[1367] In this case, the alcohol is first converted to the iodide, which is reduced. For other indirect reductions of OH, see **19-59**.

The mechanisms of most alcohol reductions are obscure.[1368] Hydrogenolysis of benzyl alcohols can give inversion or retention of configuration, depending on the catalyst.[1369] The mechanism of electroreduction of allylic alcohols in acidic aqueous media has been examined.[1370]

Note that tertiary benzylic alcohols are cleaved to give the aromatic compound [$ArC(OH)Ar'_2 \rightarrow$ Ar-H] by heating with cesium carbonate and $Pd(OAc)_2$.[1371]

OS **I**, 224; **IV**, 25, 218, 482; **V**, 339; **VI**, 769.

19-55 Reduction of Phenolic and Other Hydroxyaryl Compunds

Hydro-de-hydroxylation or Dehydroxylation, etc.

$$\text{ArOH} \xrightarrow{\text{Zn}} \text{ArH}$$

Oxygenated compounds, such as phenols, phenolic esters, and ethers, can be reduced.[1372] Phenols can be reduced by distillation over zinc dust or with HI and red phosphorus, but these methods are quite poor and are seldom feasible. Catalytic hydrogenation has also been used, but the corresponding cyclohexanol (see **15-13**) is a side product.[1373]

19-56 Replacement of Alkoxyl by Hydrogen

Hydro-de-alkoxylation or Dealkoxylation

$$R{-}O{-}R' \longrightarrow R{-}H + R'{-}H$$

R, R′ = allyl, aryl, vinyl, benzylic

Simple ethers are not normally cleaved by reducing agents, although such cleavage has sometimes been reported[1377] (e.g., THF treated with $LiAlH_4{-}AlCl_3$[1378] or with a mixture of LiAlH(*O*—*t*-Bu)$_3$ and Et_3B[1379] gave 1-butanol; the latter reagent also cleaves methyl alkyl ethers).[1380] Certain types of ethers can be cleaved quite well by reducing agents.[1381] Among these are allyl aryl,[1382] vinyl aryl,[1383] benzylic ethers,[1349,1384] and anisole[1385] (for epoxides, see **19-35**). 7-Oxobicyclo[2.2.1]heptanes

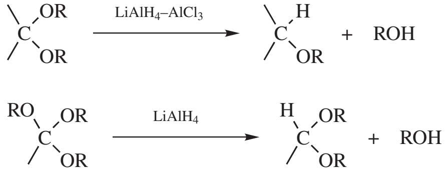
can be reductively cleaved with DIBAL and nickel catalysts.[1386] α-Methoxy ketones are demethoxylated (O=C—COMe → O=C—CH) with SmI_2.[1387]



Acetals and ketals are resistant to $LiAlH_4$ and similar hydrides, and carbonyl groups are often converted to acetals or ketals for protection (**16-5**). However, a combination of $LiAlH_4$ and $AlCl_3$[1388] does reduce acetals and ketals, removing one group, as shown above.[1389] The actual reducing agents in this case are primarily chloroaluminum hydride (AlH_2Cl) and dichloroaluminum hydride ($AlHCl_2$), which are formed from the reagents.[1390] This conversion can also be accomplished with DIBALH,[1391] as well as with other reagents.[1392] Ortho esters are easily reduced to acetals by $LiAlH_4$ alone, offering a route to aldehydes, which are easily prepared by hydrolysis of the acetals (**10-6**). Mixed ketals [R(OMe)OR′] can be demethoxylated (to give RHOR′) with $Bn_3SnCl/NaCHBH_3$ in the presence of AIBN.[1393]

OS **III**, 693; **IV**, 798; **V**, 303. Also see, OS **III**, 742; **VII**, 386.

19-57 Reduction of Tosylates and Similar Compounds

Hydro-de-sulfonyloxy-substitution

$$RCH_2OTs \; + \; LiAlH_4 \longrightarrow RCH_3$$

Tosylates and other sulfonates can be reduced[1394] with $LiAlH_4$,[1395] with $NaBH_4$ in a dipolar aprotic solvent,[1396] with $LiEt_3BH$, with *i*-Bu_2AlH (DIBALH),[1397] or with Bu_3SnH—NaI.[1398] The scope of the reaction seems to be similar to that of **19-53**.

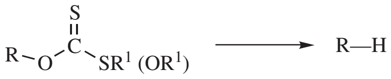
When the reagent is $LiAlH_4$, alkyl tosylates are reduced more rapidly than iodides or bromides if the solvent is Et_2O, but the order is reversed in diglyme.[1399] The reactivity difference is great enough so that a tosylate function can be reduced in the presence of a halide and vice versa. Tertiary allylcyclopropyl tosylates have been reduced with BuZnCl and a palladium catalyst.[1400]

OS **VI**, 376, 762; **VIII**, 126. See also, OS **VII**, 66.

19-58 Hydrogenolysis of esters (Barton–McCombie Reaction)

Hydro-de-thioacetoxylation



Alcohols can readily be converted to carbonate and thiocarbonate derivatives. Under radical conditions,[1401] using *azobis*-isobutyronitrile (AIBN, p. 935) and Bu_3SnH, the carbonate or thiocarbonate unit is reduced and replaced with hydrogen. The overall process is reduction of the ROH unit to RH. This is called the *Barton–McCombie reaction.*[1402] When R is cyclododecane (OCSOR), for example, this reduction yields the parent cyclododecane in 76% yield.[1403] When R = cyclododecane (OCSSMe), treatment with $Bu_3P{=}O$ and AIBN, gives the alkane in 94% yield.[1404] Both $PhSiH_3$/AIBN[1405] and $PhSiH_2$—BEt_3•O_2 can be used.[1406] This reaction can be catalytic in Bu_3SnH.[1407] Variations include reduction of ROCSNHPh derivatives using Ph_3SiH/BEt_3.[1408]

19-59 Reductive Cleavage of Carboxylic Esters

Hydro-de-acyloxylation or Deacyloxylation

The alkyl group R of certain carboxylic esters can be reduced to RH[1409] by treatment with lithium in ethylamine.[1410] The reaction is successful when R is a tertiary or a sterically hindered secondary alkyl group. A free-radical mechanism is likely.[1411] Similar reduction, also by a free-radical mechanism, has been reported with sodium in HMPA—*t*-BuOH.[1412] In the latter case, tertiary R groups give high yields of RH, but primary and secondary R are converted to a mixture of RH and ROH. Both of these methods provide an indirect method of accomplishing **19-54** for tertiary R.[1413] The same thing can be done for primary and secondary R by treating alkyl chloroformates, ROCOCl, with tri-*n*-propylsilane in the presence of *tert*-butylperoxide[1414] and by treating thiono ethers ROC(=S)W (where W can be OAr or other groups) with Ph_2SiH_2[1415] or Ph_3SiH[1416] and a free-radical initiator. Allylic acetates can be reduced with $NaBH_4$ and a palladium complex,[1417] and with $SmI_2Pd(0)$.[1418] The last reagent converts propargylic acetates to allenes $R^1C{=}C{=}CR^2R^3OAc \rightarrow R^1CH{=}C{=}CR^2R^3$.[1418] For other carboxylic ester reductions, see **19-62**, **19-38**, and **19-65**.

Note that acid chlorides can be reduced (R—COCl → R—H) using $(Me_3Si)_3SiH$/AIBN.[1419]

OS **VII**, 139.

19-60 Reduction of Hydroperoxides and Peroxides

$$\text{R—O—O—H} \xrightarrow{\text{LiAlH}_4} \text{ROH}$$

Hydroperoxides can be reduced to alcohols with $LiAlH_4$ or Ph_3P[1420] or by catalytic hydrogenation. This functional group is very susceptible to catalytic

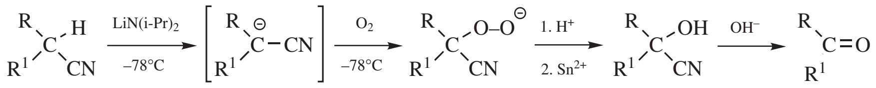
hydrogenation, as shown by the fact that a double bond may be present in the same molecule without being reduced.[1421]



The reaction is an important step in a method for the oxidative decyanation of nitriles containing an α hydrogen.[1422] The nitrile is first converted to the α-hydroperoxy nitrile by treatment with base at −78°C followed by O_2. The hydroperoxy nitrile is then reduced to the cyanohydrin, which is cleaved (the reverse of **16-52**) to the corresponding ketone. The method is not successful for the preparation of aldehydes (R′ = H).

Peroxides are cleaved to 2 equivalents of alcohols by $LiAlH_4$, Mg/MeOH,[1423] or by catalytic hydrogenation. Peroxides can be reduced to ethers with $P(OEt)_3$.[1424] In a similar reaction, disulfides (RSSR′) can be converted to sulfides RSR′ by treatment with tris(diethylamino)phosphine, $(Et_2N)_3P$.[1425]

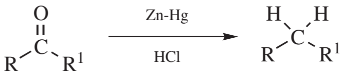
19-61 Reduction of Carbonyl to Methylene in Aldehydes and Ketones

Dihydro-de-oxo-bisubstitution



There are various ways of reducing the C=O group of aldehydes and ketones to CH_2.[1426] The two oldest, but still very popular, methods are the *Clemmensen reduction*[1427] and the *Wolff–Kishner reduction*. The Clemmensen reduction consists of heating the aldehyde or ketone with zinc amalgam and aq. HCl.[1428] Ketones are reduced more often than aldehydes. In the Wolff–Kishner reduction,[1429] the aldehyde or ketone is heated with hydrazine hydrate and a base (usually NaOH

or KOH). The *Huang–Minlon modification*[1430] of the Wolff–Kishner reaction, in which the reaction is carried out in refluxing diethylene glycol, has completely replaced the original procedure. A microwave-assisted Huang–Minlon procedure has been reported.[1431] The reaction can also be carried out under more moderate conditions (room temperature) in DMSO with potassium *tert*-butoxide as base.[1432] A new modification of the reduction treats a ketone with hydrazine in toluene with microwave irradiation, and subsequent reaction with KOH with microwave irradiation completes the Wolff–Kishner reduction.[1433] The Wolff–Kishner reaction can also be applied to the semicarbazones of aldehydes or ketones. The Clemmensen reduction is usually easier to perform, but it fails for acid-sensitive and high-molecular-weight substrates. For these cases, the Wolff–Kishner reduction is quite useful. For high-molecular-weight substrates, a modified Clemmensen reduction, using activated zinc and gaseous HCl in an organic solvent, such as ether or acetic anhydride, has proved successful.[1434] The Clemmensen and Wolff–Kishner reactions are complementary, since the former uses acidic and the latter basic conditions.

Both methods are fairly specific for aldehydes and ketones and can be carried out with many other functional groups present. However, certain types of aldehydes and ketones do not give normal reduction products. Under Clemmensen conditions,[1435] α-hydroxy ketones give either ketones (hydrogenolysis of the OH, **19-54**) or alkenes, and 1,3-diones usually undergo rearrangement (e.g., $MeCOCH_2$-COMe $\rightarrow$ $MeCOCHMe_2$).[1436] Neither method is suitable for α,β-unsaturated ketones. These give pyrazolines[1437] under Wolff–Kishner conditions, while under Clemmensen conditions both groups of these molecules may be reduced or if only one group is reduced, it is the C=C bond.[1438] Sterically hindered ketones are resistant to both the Clemmensen and Huang–Minlon procedures, but can be reduced by vigorous treatment with anhydrous hydrazine.[1439] In the Clemmensen reduction, pinacols (**19-76**) are often side products.

Other reagents have also been used to reduce the C=O of aldehydes and ketones to CH_2.[1440] Among these are Me_3SiCl followed by $Et_3SiH/TiCl_4$,[1441] $Ni(OAc)_2$ on borohydride exchange resin,[1442] Et_3SiH on pyridinium poly(hydrogen fluoride),

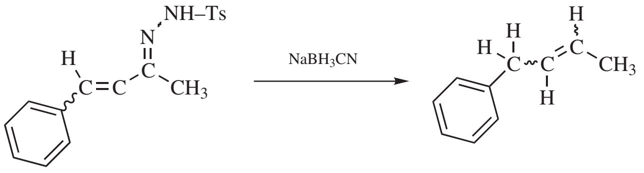
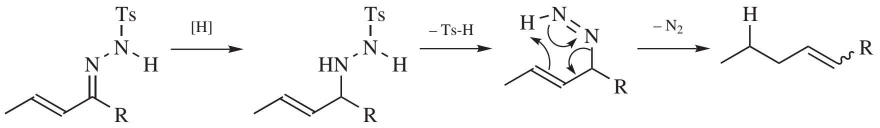
An indirect method of accomplishing the reaction is reduction of tosylhydrazones ($R_2C{=}N{-}NHTs$) to R_2CH_2 with $NaBH_4$, BH_3, catecholborane, bis(benzyloxy)borane, or $NaBH_3CN$. The reduction of α,β-unsaturated tosylhydrazones with $NaBH_3CN$, with $NaBH_4$-HOAc, or with catecholborane proceeds with migration of the double bond to the position formerly occupied by the carbonyl carbon, even if this removes the double bond from conjugation with an aromatic ring,[1462] for example,



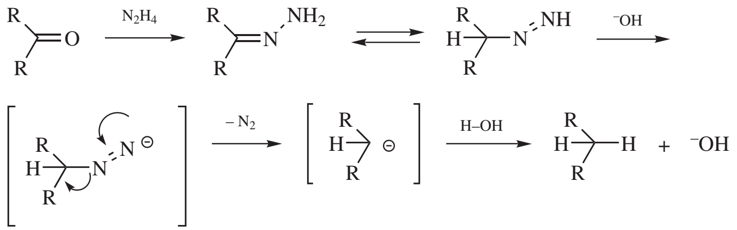
A cyclic mechanism is apparently involved:



Another indirect method is conversion of the aldehyde or ketone to a dithioacetal or ketal, and desulfurization of using Raney nickel or another reagent (**14-27**).

It is interesting to see that amines can be deaminated to give the corresponding methylene compounds with low-valent titanium ($TiCl_3$/Li/THF).[1463]

The first step in the mechanism[1464] of the Wolff–Kishner reaction consists of formation of the hydrazone (**16-14**). It is this species that undergoes reduction in the presence of base, most likely in the following manner:



[1462]Kabalka, G.W.; Yang, D.T.C.; Baker, Jr., J.D. *J. Org. Chem.* ***1976***, *41*, 574; Taylor, E.J.; Djerassi, C. *J. Am. Chem. Soc.* ***1976***, *98*, 2275; Hutchins, R.O.; Natale, N.R. *J. Org. Chem.* ***1978***, *43*, 2299; Greene, A.E. *Tetrahedron Lett.* ***1979***, 63.

Not much is known about the mechanism of the Clemmensen reduction. Several mechanisms have been proposed,[1465] including one going through a zinc–carbene intermediate.[1466] One thing reasonably certain is that the corresponding alcohol is not an intermediate, since alcohols prepared in other ways fail to give the reaction. Note that the alcohol is not an intermediate in the Wolff–Kishner reduction either.

19-62 Reduction of Carboxylic Esters to Ethers

Dihydro-de-oxo-bisubstitution

$$RCOOR' \xrightarrow[\text{LiAlH}_4]{\text{BF}_3\text{–etherate}} RCH_2OR'$$

Carboxylic esters and lactones have been reduced to ethers, although 2 equivalents of alcohol are more commonly obtained (**19-38**). Reduction to ethers has been accomplished with a reagent prepared from BF_3–etherate and either $LiAlH_4$, $LiBH_4$, or $NaBH_4$,[1467] with trichlorosilane and uv light,[1468] and with catalytic hydrogenation. The reaction with the BF_3 reagent apparently succeeds with secondary R′, but not with primary R′, which give **19-38**. Lactones give cyclic ethers.[1469] Acyloxy groups are reduced by cleavage of the C—C=O bond, R(Ar)COO—C → C—H) with an excess of Ph_2SiH_2 and di-*tert*-butyl peroxide.[1470] Esters are reduced to ethers using Et_3SiH and $TiCl_4$.[1471] Lactones are converted to cyclic ethers by treatment with Cp_2TiCl_2 followed by Et_3SiH on Amberlyst 15.[1472]

Thiono esters RCSOR′ can be reduced to ethers RCH_2OR' with Raney nickel (**14-27**).[1473] Reaction of thio esters, such as C—OC(=O)Ph with Ph_2SiH_2 and Ph_3SnH with BEt_3, followed by AIBN (p. 935) leads to reduction of the C=S unit to give an ether.[1474] Since the thiono esters can be prepared from carboxylic

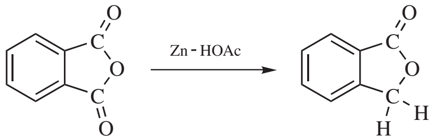
esters (**16-11**), this provides an indirect method for the conversion of carboxylic esters to ethers. Thiol esters (RCOSR′) have been reduced to thioethers (RCH_2SR').[1475]

See also, **19-65**, **19-59**.

19-63 Reduction of Cyclic Anhydrides to Lactones and Acid Derivatives to Alcohols

Dihydro-de-oxo-bisubstitution



Cyclic anhydrides can give lactones if reduced with Zn—HOAc, with hydrogen and platinum or $RuCl_2(Ph_3P)_3$,[1476] with $NaBH_4$,[1477] or even with $LiAlH_4$, although with the last-mentioned reagent diols are the more usual product. With a BINOL–AlHOEt complex, however, reduction to the lactone proceeds smoothly.[1478] With some reagents the reaction can be accomplished regioselectively, that is, only a specific one of the two C=O groups of an unsymmetrical anhydride is reduced.[1479] Open-chain anhydrides either are not reduced at all (e.g., with $NaBH_4$) or give 2 equivalents of alcohol. The $LiAlH_4$ usually reduces open-chain anhydrides to give 2 equivalents of alcohol. With cyclic anhydrides the reaction with $LiAlH_4$ can be controlled to give either diols or lactones.[1480] The $NaBH_4$ in THF, with dropwise addition of methanol, reduces open-chain anhydrides to 1 equivalent of primary alcohol and 1 equivalent of carboxylic acid.[1481]

Acyl halides are reduced[1482] to alcohols by $LiAlH_4$ or $NaBH_4$, as well as by other metal hydrides (Table 19.5), but not by borane.

In general, reduction of amides to alcohols is difficult. More commonly the amide is reduced to an amine. An exception uses LiH_2NBH_3 to give the alcohol.[1483] Reduction with sodium metal in propanol also gives the alcohol.[1484] Acyl

imidazoles are also reduced to the corresponding alcohol with $NaBH_4$ in aq. HCl.[1485]

There are no *Organic Syntheses* references, but see OS **II**, 526, for a related reaction. See OS **VI**, 482 for reduction to alcohols and OS **IV**, 271 for reduction of acyl halides.

19-64 Reduction of Amides to Amines

Dihydro-deoxo-bisubstitution

$$RCONH_2 \xrightarrow{LiAlH_4} RCH_2NH_2$$

Amides can be reduced[1486] to amines with $LiAlH_4$ or by catalytic hydrogenation, but high temperatures and pressures are usually required for the latter. Even with $LiAlH_4$, the reaction is more difficult than the reduction of most other functional groups, and other groups often can be reduced without disturbing an amide function. Although $NaBH_4$ by itself does not reduce amides, it does so in the presence of certain other reagents[1487] including iodine.[1488] Lithium borohydride reduces acetamides.[1489] Substituted amides can be reduced with these powerful reagents; secondary amides to secondary amine and tertiary amides to tertiary amines. Borane[1490] and sodium in 1-propanol[1491] are good reducing agents for all three types of amides. Another reagent that reduces disubstituted amides to amines is trichlorosilane.[1492] Other silanes, such as Et_3SiH in the presence of a rhenium catalyst, reduce amides to amines.[1493] Sodium (dimethylamino)borohydride reduces unsubstituted and disubstituted, but not monosubstituted amides.[1494] Electrolytic reduction of carbamates to give an amine are possible.[1495]

With some RCONR, $LiAlH_4$ causes cleavage, and the aldehyde (**10-41**) or alcohol is obtained. Lithium triethylborohydride produces the alcohol with most *N,N*-disubstituted amides, but not with unsubstituted or *N*-substituted amides.[1496] Lactams are reduced to cyclic amines in high yields with $LiAlH_4$, although cleavage sometimes occurs here too. A mixture of $LiBHEt_3/Et_3SiH$ is also effective.[1497] Lactams are also reduced to cyclic amines with 9-BBN[1498] (p. 1077) or $LiBH_3NMe_2$.[1499] Imides are generally reduced on both sides,[1500] although it is sometimes possible to stop with just one. Both cyclic and acyclic imides have been reduced in this manner, although with acyclic imides cleavage is often obtained, for example,[1501]

$$PhN(COMe)_2 \longrightarrow PhNHEt$$

Acyl sulfonamides have been reduced ($RCONHSO_2Ph \rightarrow RCH_2NHSO_2Ph$) with BH_3—SMe_2[1502] and with SmI_2/DMPU.[1503]

OS **IV**, 339, 354, 564; **VI**, 382; **VII**, 41.

19-65 Reduction of Carboxylic Acids and Esters to Alkanes

Trihydro-de-alkoxy,oxo-tersubstitution, and so on.

$$RCOOR' \xrightarrow{(C_5H_5)_2TiCl_2} RCH_3 + R'OH$$

The reagent titanocene dichloride reduces carboxylic esters in a different manner from that of **19-59**, **19-62**, or **19-38**. The products are the alkane RCH_3 and the alcohol R′OH.[909] The mechanism probably involves an alkene intermediate. Aromatic acids can be reduced to methylbenzenes by a procedure involving refluxing first with trichlorosilane in MeCN, then with tripropylamine added, and finally with KOH and MeOH (after removal of the MeCN).[1504] The following sequence has been suggested:[1504]

$$ArCOOH \xrightarrow{SiHCl_3} (ArCO)_2O \xrightarrow[R_3N]{SiHCl_3} ArCH_2SiCl_3 \xrightarrow[MeOH]{KOH} ArCH_3$$

Esters of aromatic acids are not reduced by this procedure, so an aromatic COOH group can be reduced in the presence of a COOR′ group.[1505] However, it is also

possible to reduce aromatic ester groups, by a variation of the trichlorosilane procedure.[1506] Both *o*- and *p*-hydroxybenzoic acids and their esters have been reduced to cresols $HOC_6H_4CH_3$ with sodium bis(2-methoxyethoxy)aluminum hydride, $NaAlH_2(OC_2H_4OMe)_2$ (Red-Al).[1507] Heating a 2-pyridylbenzyl ester with ammonium formate and a rutheniumc atlyst leads to reduction of the CH_2COO unit to the the alkane.[1508]

Carboxylic acids can also be converted to alkanes, indirectly,[1509] by reduction of the corresponding tosylhydrazides $RCONHNH_2$ with $LiAlH_4$ or borane.[1510]

OS **VI**, 747.

19-66 Hydrogenolysis of Nitriles

Hydro-de-cyanation

$$R{-}CN \longrightarrow R{-}H$$

This transformation is not common, but given the proliferation of nitriles in organic chemistry, it is potentially quite useful. In the presence of mercuric compounds, tertiary nitriles can be reduced to the hydrocarbon with sodium cyanoborohydride.[1511] *gem*-Dinitriles can be reduced to the corresponding mononitrile with SmI_2.[1512]

19-67 Reduction of the C—N Bond

Hydro-de-amination or Deamination

$$RNH_2 \longrightarrow RH$$

Benzylic amines are particularly susceptible to hydrogenolysis by catalytic hydrogenation[1513] or dissolving metal reduction.[1514] Note that the Wolff–Kishner reduction in **19-61** involved formation of a hydrazone and deprotonation by base led to loss of nitrogen and reduction. Ceric ammonium nitrate in aqueous acetonitrile has also been shown to reductively cleave the *N*-benzyl group.[1515] Primary amines have been reduced to RH with hydroxylamine-*O*-sulfonic acid and

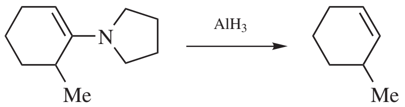
aq. NaOH to give the hydrocarbon, nitrogen gas, and the sulfate anion.[1516] It is postulated that R—N=N—H is an intermediate that decomposes to the carbocation. The reaction has also been accomplished with difluoroamine HNF_2;[1517] the same intermediates are postulated in this case. Treatment of aniline with 20 equivalents of NO gave benzene.[1518] An indirect means of achieving the same result is the conversion of the primary amine to the sulfonamide, $RNHSO_2R'$ (**16-102**), and treatment of this with NH_2OSO_2OH[1519] or NaOH, and then NH_2Cl.[1520] Tosylaziridines derived from terminal alkenes are reduced to the corresponding primary tosylamine with polymethylhydrosiloxane/Pd—C.[1521]

Other indirect methods involve reduction of *N,N*-ditosylates (p. 497) with $NaBH_4$ in HMPA[1522] and modifications of the Katritzky pyrylium–pyridinium method.[1523] Allylic and benzylic amines[1349] can be reduced by catalytic hydrogenolysis. Aziridines can be reductively opened with SmI_2[1524] or with Bu_3SnH and AIBN.[1525] The C—N bond of enamines is reductively cleaved to give an alkene with alane (AlH_3).[1526]



and with 9-BBN (p. 1077) or borane methyl sulfide (BMS).[1527] Since enamines can be prepared from ketones (**16-13**), this is a way of converting ketones to alkenes. In the latter case, BMS gives retention of configuration [an (*E*) isomer gives the (*E*) product], while 9-BBN gives the other isomer.[1527] Diazo ketones are reduced to methyl ketones by HI: $RCOCHN_2 + HI \rightarrow RCOCH_3$.[1528]

Quaternary ammonium salts can be cleaved with $LiAlH_4$, $R_4N^+ + LiAlH_4 \rightarrow R_3N + R^-$, as can quaternary phosphonium salts R_4P^+. Other reducing agents have also been used, for example, lithium triethylborohydride (which preferentially cleaves methyl groups)[1529] and sodium in liquid ammonia. When quaternary salts

are reduced with sodium amalgam in water, the reaction is known as the *Emde reduction*. However, this reagent is not applicable to the cleavage of ammonium salts with four *saturated* alkyl groups. Of course, aziridines[899] can be reduced in the same way as epoxides (**19-35**).

Nitro compounds, RNO_2, can be reduced to RH[1530] by sodium methylmercaptide, CH_3SNa, in an aprotic solvent[1531] or by Bu_3SnH.[1532] Both reactions have free-radical mechanisms.[1533] Tertiary nitro compounds can be reduced to RH by NaHTe.[1534] Hydrogenolysis with a Pt catalyst in the gas phase has been reported to reduce nitro compounds, as well as primary and secondary amines.[1535] The nitro group of aromatic nitro compounds has been removed with sodium borohydride.[1536] This reaction involves an addition–elimination mechanism. Reduction of the C—N bond on aromatic amines with Li metal in THF generates the aryl compounds.[1537] Sodium nitrite, sodium bisulfite in EtOH/water/acetic acid does a similar reduction.[1538] Conversion of the aniline derivative to the methanesulfonamide and subsequent treatment with NaH and NH_2Cl gives the same result.[1539] The Bu_3SnH reagent also reduces isocyanides, RNC (prepared from RNH_2 by formylation followed by **17-31**), to RH,[1540] a reaction that can also be accomplished with Li or Na in liquid NH_3,[1541] or with K and a crown ether in toluene.[1542] α-Nitro ketones can be reduced to ketones with $Na_2S_2O_4$—Et_3SiH in HMPA—H_2O.[1543]

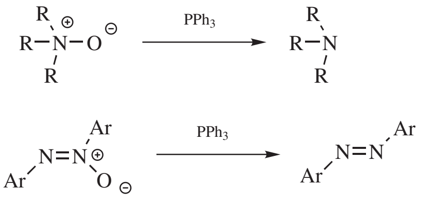
19-68 Reduction of Amine Oxides and Azoxy Compounds

N-Oxygen-detachment



Amine oxides[1544] and azoxy compounds (both alkyl and aryl)[1545] can be reduced practically quantitatively with triphenylphosphine.[1546] Other reducing agents, for example, $LiAlH_4$, $NaBH_4/LiCl$,[1547] H_2—Ni, PCl_3, $TiCl_3$,[1548] Ga/H_2O,[1549] In/$TiCl_4$,[1550] $LiAlH_4/TiCl_4$, or $SbCl_2$ have also been used. Indium metal with aqueous ammonium chloride in methanol gives good yields of pyridine from pyridine *N*-oxide.[1551] Similar results are obtained using ammonium formate and Raney nickel[1552] or zinc.[1553] Indium (III) chloride has been used for the reduction of quinoline *N*-oxide to quinoline.[1554] Polymethylhydrosiloxane with Pd—C is also an effective reducing agent for amino oxides.[1555] Nitrile oxides[1556] ($R{-}C{\equiv}N^+{-}O^-$) can be reduced to nitriles with trialkylphosphines,[1557] and isocyanates (RNCO) to isocyanides (RNC) with Cl_3SiH—Et_3N.[1558]

Analogous to amino *N*-oxides, phosphine oxides ($R_3P{=}O$) are reduced to phosphines (R_3P). Treatment of a phosphine oxide with MeOTf followed by reduced

19-69 Replacement of the Diazonium Group by Hydrogen

Dediazoniation or **Hydro-de-diazoniation**

$$ArN_2^+ + H_3PO_2 \longrightarrow ArH$$

Reduction of the diazonium group (*dediazoniation*) provides an indirect method for the removal of an amino group from an aromatic ring.[1561] The best and most common way of accomplishing this is by use of hypophosphorous acid H_3PO_2, although many other reducing agents[1562] have been used, among them ethanol, HMPA,[1563] thiophenol,[1564] and sodium stannite. Ethanol was the earliest reagent used, and it frequently gives good yields, but often ethers (ArOEt) are side products. When H_3PO_2 is used, 5–15 equivalents of this reagent are required per equivalent of substrate. Diazonium salts can be reduced in nonaqueous media by several methods, including treatment with Bu_3SnH or Et_3SiH in ethers or MeCN[1565] and by isolation as the BF_4^- salt and reduction of this with $NaBH_4$ in DMF.[1566] Aromatic amines can be deaminated ($ArNH_2 \longrightarrow ArH$) in one laboratory step by treatment with an alkyl nitrite in DMF[1567] or boiling THF.[1568] The corresponding diazonium salt is an intermediate.

Not many investigations of the mechanism have been carried out. It is generally assumed that the reaction of diazonium salts with ethanol to produce ethers takes place by an ionic (S_N1) mechanism while the reduction to ArH proceeds by a free-radical process.[1569] The reduction with H_3PO_2 is also believed to have a free-radical mechanism.[1570] In the reduction with $NaBH_4$, an aryldiazene intermediate

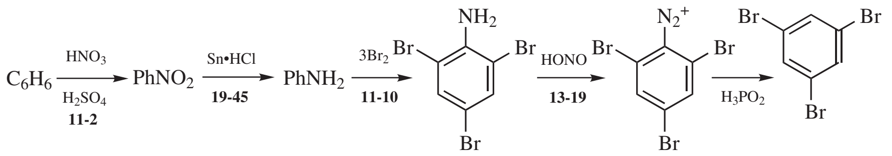
(ArN=NH) has been demonstrated,[1571] arising from nucleophilic attack by BH_4^- on the β nitrogen. Such diazenes can be obtained as moderately stable (half-life of several hours) species in solution.[1572] It is not entirely clear how the aryldiazene decomposes, but there are indications that either the aryl radical AR• or the corresponding anion Ar^- may be involved.[1573]

An important use of the dediazoniation reaction is to remove an amino group after it has been used to direct one or more other groups to ortho and para positions. For example, the compound 1,3,5-tribromobenzene cannot be prepared by direct bromination of benzene because the bromo group is ortho–para-directing; however, this compound is easily prepared by the following sequence:



Many other compounds that would otherwise be difficult to prepare are easily synthesized with the aid of the dediazoniation reaction.

Unwanted dediazoniation can be suppressed by using hexasulfonated calix[6]arenes (see p. 122).[1574]

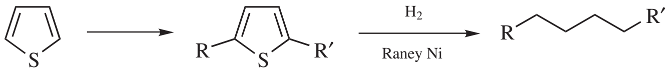
Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, including disulfides, thiono esters,[1577] thioamides, sulfoxides, and thioacetals.[1578] Reduction of thioacetals is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see **19-61**), and it can also give the alkene if a hydrogen is present.[1579] In most of the examples given, R can also be aryl. Other reagents[1580] have also been used.[1581]

Lithium aluminum hydride reduces most sulfur compounds with cleavage of the C—S bond, including thiols.[1582] Thioesters can be reduced with Ni_2B (from $NiBr_2/NaBH_4$).[1583] β-Ketosulfones are reduced with $TiCl_4$—Zn,[1584] $TiCl_4$—Sm,[1585] or Bu_3SnCl—$NaCNBH_3$/AIBN.[1586]

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene to **49**, followed by reduction to give **50**.



49 **50**

Thiophenes can also be desulfurized to alkenes ($RCH_2CH{=}CHCH_2R'$ from **49**) with a nickel boride catalyst prepared from nickel(II) chloride and $NaBH_4$ in methanol.[1587] It is possible to reduce just one SR group of a dithioacetal by treatment with borane–pyridine in trifluoroacetic acid or in CH_2Cl_2 in the presence of $AlCl_3$.[1588] Phenyl selenides RSePh can be reduced to RH with Ph_3SnH[1589] and with nickel boride.[1590] Cleavage of the C—Se bond can also be achieved with SmI_2.[1591]

The exact mechanism of the Raney nickel reactions are still in doubt, although they are probably of the free-radical type.[1592] It has been shown that reduction of thiophene proceeds through butadiene and butene, not through 1-butanethiol or other sulfur compounds, that is, the sulfur is removed before the double bonds are reduced. This was demonstrated by isolation of the alkenes and the failure to isolate any potential sulfur-containing intermediates.[1593]

Sulfonamides are reduced to the corresponding amine by heating with Me_3SiCl and NaI.[1594]

19-71 Reduction of Sulfonyl Halides and Sulfonic Acids to Thiols or Disulfides

$$RSO_2Cl \xrightarrow{LiAlH_4} RSH$$

Thiols can be prepared by the reduction of sulfonyl halides[1595] with $LiAlH_4$. Usually, the reaction is carried out on aromatic sulfonyl chlorides. Zinc and acetic acid, and HI, also give the reduction. Another reagent for this reduction is Me_2SiCl_2 and Zn with dimethyl acetamide.[1596] Sulfonic acids have been reduced to thiols with a mixture of triphenylphosphine and either I_2 or a diaryl disulfide.[1597] For the reduction of sulfonyl chlorides to sulfinic acids, see **16-104**.

Disulfides RSSR can also be produced.[1598] Other sulfonic acid derivatives can be converted to disulfides. Esters, such as PhSAc, are converted to disulfides PhS—SPh with Clayan and microwave irradiation.[1599] Thiobenzoate derivatives PhSBz are similarly converted to PhS—SPh with SmI_2.[1600] In a similar manner, RS—SO_3Na is converted to RS—SR when heated with samarium metal in water.[1601]

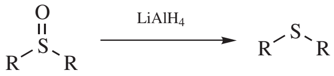
19-72 Reduction of Sulfoxides and Sulfones

S-Oxygen-detachment



Sulfoxides can be reduced to sulfides by many reagents,[1602] among them Ph_3P,[1603] $LiAlH_4$, HI, Bu_3SnH,[1604] $MeSiCl_3$—NaI,[1605] H_2—Pd—C,[1606] $NaBH_4$—$NiCl_2$,[1607] $NaBH_4/I_2$,[1608] catecholborane,[1609] TiI_4,[1610] $TiCl_4$/In,[1611] Cp_2TiCl_2/In,[1612] Sm/methanolic NH_4Cl with ultrasound,[1613] $(EtO)_2PCl/NEt_3$,[1614] and $SiO_2/SOCl_2$. Sulfones, however, are usually stable to reducing agents, although they have been reduced to sulfides with DIBALH, $(i\text{Bu})_2AlH$.[1615] A less general reagent is $LiAlH_4$, which reduces some sulfones to sulfides, but not others.[1616] Heating sulfoxides with 2,6-dihydroxypyridine gives the corresponding sulfide.[1617] Both sulfoxides and sulfones can be reduced by heating with sulfur (which is oxidized to SO_2), although the reaction with sulfoxides proceeds at a lower temperature. It has been shown by using substrate labeled with ^{35}S that sulfoxides simply give up the oxygen to the sulfur, but that the reaction with sulfones is more complex, since $\sim$ 75% of the original radioactivity of the sulfone is lost.[1618] This indicates that most of the sulfur in the sulfide product comes in this case from the *reagent*. There is no direct general

method for the reduction of sulfones to sulfoxides, but an indirect method has been reported.[1619] Selenoxides can be reduced to selenides with a number of reagents.[1620]

OS IX, 446

D. Reduction With Cleavage

19-73 de-Alkylation of Amines and Amides

$$R'_2N{-}R \longrightarrow R'_2N{-}H$$

Certain amines can be dealkylated, usually under reductive conditions. *N*-Allyl amines, $R_2N{-}CH_2CH{=}CH_2$ are converted to the corresponding amine, $R_2N{-}H$, with Dibal/$NiCl_2$dppp,[1621] and with Pd(dba)$_2$dppb.[1622] A mixture of $TiCl_3$ and Li converts *N*-benzylamines to the amine ($R_2NCH_2Ph \rightarrow R_2NH$).[1623] In the case of *N,N*-dimethyl amines, $RuCl_3$ and H_2O_2 demethylate the amine ($ArNMe_2 \rightarrow ArNHMe$).[1624] Tribenzylamines are dealkylated to give the dibenzylamine with ceric ammonium nitrate in aqueous acetonitrile.[1625] *N*-Benzyl indoles are cleaved to indoles with O_2, DMSO/KO*t*-Bu[1626] or with tetrabutylammonium fluoride.[1627]

The process is not limited to amines. Amides can also be dealkylated. *N*-Benzyl amides are debenzylated in the presence of NBS and AIBN.[1628]

N-Alkyl sulfonamides are dealkylated with PhI(OAc)$_2$ and I_2 with ultrasound to give a primary sulfonamide.[1629] Similar results are obtained with H_5IO_6 and a chromium catalyst.[1630] *tert*-Butyl sulfonamides are cleaved to the primary sulfonamide with BCl_3.[1631]

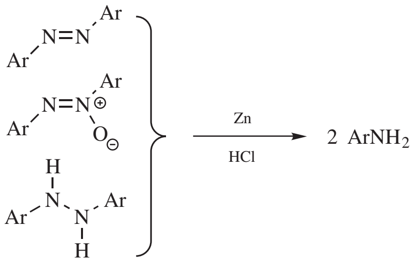
19-74 Reduction of Azo, Azoxy, and Hydrazo Compounds to Amines



Azo, azoxy, and hydrazo compounds can all be reduced to amines.[1632] Metals (notably zinc) and acids, and $Na_2S_2O_4$, are frequently used as reducing agents, and Bu_3SnH with a copper catalyst has been used.[1633] Borane reduces azo compounds to amines, although it does not reduce nitro compounds.[1634] $LiAlH_4$ does not reduce hydrazo compounds or azo compounds, although with the latter, hydrazo compounds are sometimes isolated. With azoxy compounds, $LiAlH_4$ gives only azo compounds (**19-68**). Noted that azo compounds are reduced to the hydrazine by reaction with hydrazine hydrate in ethanol.[1635]

19-75 Reduction of Disulfides to Thiols

S-Hydrogen-uncoupling

Disulfides can be reduced to thiols by mild reducing agents,[1636] such as zinc and dilute acid, In and NH_4Cl/EtOH,[1637] or Ph_3P and H_2O.[1638] The reaction can also be accomplished simply by heating with alkali.[1639] Among other reagents used have been $LiAlH_4$, $NaBH_4/ZrCl_4$,[1640] Mg/MeOH,[1641] KBH(*O*—*i*Pr)$_3$,[1642] and hydrazine or substituted hydrazines.[1643]

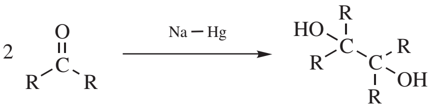
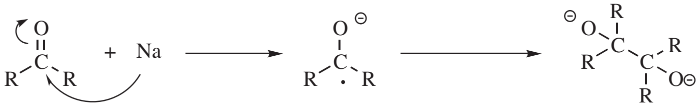
E. Reductive Coupling

19-76 Bimolecular Reduction of Aldehydes and Ketones to 1,2-Diols and Imines to 1,2-Diamines

2/*O*-Hydrogen-coupling and 2/*N*-Hydrogen-coupling



1,2-Diols (pinacols) can be synthesized by reduction of aldehydes and ketones with active metals, such as sodium, magnesium, or aluminum.[1645] Aromatic ketones give better yields than aliphatic ones. The use of a Mg—MgI_2 mixture has been called the *Gomberg–Bachmann pinacol synthesis*.[1646] As with a number of other reactions involving sodium, there is a direct electron transfer here, converting the ketone or aldehyde to a ketyl, which dimerizes.



Other reagents have been used,[1647] including Sm,[1648] Yb,[1649] Yb-Me_3SiCl,[1650] $InCl_3$ catalyst with Mg,[1651] Al/$TiCl_3$,[1652] $VOCl_3$ catalyst with Me_3SiCl,[1653]

activated Mn,[1654] In with ultrasound,[1655] Zn,[1656] and a reagent prepared from $TiCl_4$[1657] and Mg amalgam[1658] (a low-valent titanium reagent;[1659] see **19-76**). A mixture of $TiCl_4$[1660] or $TiCl_2$[1661] and Zn can also be used. Unsymmetrical coupling between two different aldehydes has been achieved by the use of a vanadium complex,[1662] while $TiCl_3$ in aqueous solution has been used to couple two different ketones.[1663] Two aldehydes have also been coupled using magnesium in water.[1664] Coupling leads to a mixture of syn- and anti-diols. "Syn-selective" reagents are Cp_2TiCl_2/Mn,[1665] $TiCl_4/Bu_4I$,[1666] TiI_4,[1667] $TiBr_2$+Cu,[1668] and $NbCl_3$.[1669] With SmI_2,[1670] coupling in the presence of a primary alkyl iodide leads to acyl addition using an excess of HMPA, but pinacol coupling with an excess of LiBr.[1671] "Anti-selective" coupling reactions are also known: Ti–salen,[1672] Mg with a $NiCl_2$ catalyst,[1673] Sm/$SmCl_3$,[1674] and $TiCl_4(thf)_2$ with a chiral Schiff base.[1675] Aryl

aldehydes are coupled to give the bis-trimethylsilyl ether using Mn, Me_3SiCl, and Cp_2TiCl_2.[1676]

A crossed-pinacol coupling was reported using Et_2Zn and with a BINOL catalyst gave good enantioselectivity.[1677] A combination of Mg and Me_3SiCl was also used to a crossed-pinacol.[1678]

Intramolecular pinacol coupling reactions are known, giving cyclic 1,2-diols.[1679] Dialdehydes have been cyclized by reaction with $TiCl_3$ to give cyclic 1,2-diols in good yield.[1680] A radical-induced coupling of an α,ω-dialdehyde led to *cis*-1,2-cyclopentanediol when treated with Bu_3SnH and AIBN.[1681] or induced photochemically.[1682]

Chiral additives with pinacol couplings lead to formation of a diol with moderate to good enantioselectivity.[1683] Chiral metal complexes in conjunction with a metal leads to diol formation with good enantioselectivity.[1684]

A variation of the pinacol coupling treats acyl nitriles with indium metal and ultrasound to give a 1,2-diketone.[1685] Another variation couples acetals to give 1,2-diols.[1686]

The dimerization of ketones to 1,2-diols can also be accomplished photochemically; indeed, this is one of the most common photochemical reactions.[1687] The substrate, which is usually a diaryl or aryl alkyl ketone (though a few aromatic aldehydes and dialkyl ketones have been dimerized), is irradiated with UV light in the presence of a hydrogen donor, such as isopropyl alcohol, toluene, or an amine.[1688]

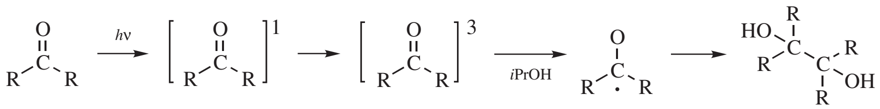
[1688]For a review of amines as hydrogen donors in this reaction, see Cohen, S.G.; Parola, A.; Parsons, Jr., G.H. *Chem. Rev.* ***1973***, *73*, 141.

In the case of benzophenone, irradiated in the presence of 2-propanol, the ketone molecule initially undergoes $n \rightarrow \pi^*$ excitation, and the singlet species thus formed crosses to the T_1 state with a very high efficiency.



Singlet Triplet **51**

The T_1 species abstracts hydrogen from the alcohol (p. 347), and then dimerizes. The *i*PrO• radical, which is formed by this process, donates H• to another molecule of ground-state benzophenone, producing acetone and another molecule of **51**. This mechanism[1689] predicts that the quantum yield for the disappearance of benzophenone should be 2, since each quantum of light results in the conversion of 2 equivalents of benzophenone to **51**. Under favorable experimental conditions, the observed quantum yield does approach 2. Benzophenone abstracts hydrogen with very high efficiency. Other aromatic ketones are dimerized with lower quantum yields, and some (e.g., *p*-aminobenzophenone, *o*-methylacetophenone) cannot be dimerized at all in 2-propanol (although *p*-aminobenzophenone, e.g., can be dimerized in cyclohexane[1690]). The reaction has also been carried out electrochemically.[1691]
